THURSDAY, NOVEMBER 3, 1870

THE GOVERNMENT OF THE ROYAL SOCIETY

WE have so often maintained in these columns that Science cannot now be propelled on its onward course by the efforts of unassisted individuals only, and that the State must itself, sooner or later, put its shoulder vigorously to the wheel, that there is some danger lest we should be thought to undervalue the force of private enterprise. We, on the contrary, attach very high importance to such enterprise, which exists amongst us in England more abundantly than perhaps in any other country in the world. It exists in two forms—in that of detached individual effort, and in that of voluntarily associated bodies, the Scientific Societies. To the latter only we propose now to address ourselves.

The services that have been rendered to science by these societies infinitely surpass in kind and in amount all that has been done by means of all other agencies. By bringing together men struggling for the same goal, though often by different routes, by submitting to the arbitrament of open discussion opposite views relating to the same subject, by publishing theoretical speculations however divergent, and experimental results however discordant, and by rewarding pre-eminent services, the truth has the fairest possible chance of being elicited, and the non-scientific classes become the recipients—though often the unconscious, and therefore ungrateful, recipients—of benefits, material as well as intellectual, immeasurable in value. Sweep away what has been done for Science in England by Scientific Societies, and scarcely a trace of Science would remain. For it must not be forgotten that individual labourers, working in however isolated a manner, are largely indebted to the stores of knowledge garnered in the Proceedings of the Societies, for the very tools with which they operate.

Such being the vast importance of these bodies, their constitution and system of internal government are questions of the highest interest. We propose to confine our remarks on the present occasion to the Royal Society, the highest of all, and that which should be the pattern to all others.

In former days, election to the Royal Society was an easier matter than it is now. At present, personages of Royal blood and peers of the Realm alone have special facilities for admission. The ordinary candidates are submitted to an ordeal of considerable stringency. Virtually they are elected, though nominally only selected, by the Council, whose decisions, however, are almost invariably ratified by the Society at large. The claims to admission of each candidate are carefully and fully discussed in Council, and fifteen only are nominated by ballot each year. The number of candidates is usually about fifty. Though the Council's list of fifteen does not always give universal satisfaction, yet it must be allowed that names rarely, if ever, appear on that list whose bearers cannot point to actual scientific work performed by themselves. Such a thing as the election of a thoroughly unscientific or unintellectual man is unknown in the present day. It follows that the standard of mental power to which the Fellows of the Royal Society must, as a body, have attained, is very high. It may, indeed, be safely asserted that no corporation in the kingdom, or even in the world, can be for a moment compared for mental power with the Royal Society. So much, in briefest terms, for its constitution.

The system of internal government by which the affairs of a body like this are regulated becomes a matter of the deepest moment, not only to the Society, but to the nation and to civilisation itself.

The governing body, the Council, is composed of a President, five Vice-presidents, and twelve ordinary members. These are all honorary posts. Two ordinary Secretaries and one Foreign Secretary, members of the Council with votes, are paid, the first two 300*l*., and the last 100*l*. per annum, out of the funds of the Society. There is also a Treasurer, a member of Council, but unpaid. An Assistant Secretary and a Librarian, not members of the Council, and of course both salaried, perform all the necessary routine duties.

The Vice-presidents and ordinary members of Council sit two years only, and then retire by rotation. They cannot be re-elected until a year has elapsed since their retirement. The Presidentship is not limited as to duration, nor are the posts of Secretary, Foreign Secretary, and Treasurer.

There is a wide-spread feeling that this form of government admits of improvement, and as the actual occupants of the posts in which an alteration is thought desirable stand deservedly very high in the estimation, not of the scientific world only, but in that of the community generally, the reform of which we are about to speak can fortunately now be discussed without personality, and without any fear of the acrimony to which, under less auspicious circumstances, such a discussion would inevitably lead.

The proposed alterations are of the very simplest kind, namely, that the tenure of office of the President should coincide with that of the rest of the Council, and that the Secretaries and Foreign Secretaries should be unpaid.

The inconveniences of the present arrangement, on which our space only admits of a few words, are, first, that however efficient, impartial, and undespotic the President and officers may be, their permanent tenure of their posts for a number of years in succession must tend to constitute them, in a Council undergoing yearly change, more or less an *imperium in imperio*. Indeed, their very efficiency and mastery of rule and precedent, in themselves most valuable attributes, aggravate, as well as generate, this tendency. The practical effect necessarily is, that the President and officers naturally and unavoidably get into the way of acting together, and of bringing before the Council matters for deliberation in somewhat of a cut and dried condition. At the opening of the Session, the new members, it is well known, are naturally diffident of expressing views adverse to those thus prepared for their acceptance by such experienced hands; and it is a common remark that it is only in his second year that a member serving on the Council for the first time usually declares his sentiments with independence and freedom. The choice, therefore, seems to lie between the experience which results from long service in the chair and secretariat, and the greater scope for deliberative activity, which limited service in those posts would afford.

In deciding between the two alternatives, the character of the Council must be considered. It contains a small selected section drawn from a large highly select body, the very *crême de la crême* of the science and intellect of the kingdom, men who, one and all, are supposed to have gained their position by the most severe intellectual discipline, and who value that position as one of great responsibility and high honour. If chance, or favouritism, or money, or rank, had any appreciable influence on their election, the case would be very different. Some dry nursing might then be not amiss. But in the actual case, a Council composed of the flower of English intellect may safely be left to deliberate with unfettered republican freedom.

Another inconvenience attending the permanent, or rather unlimited, Presidentship, is one which may be indicated without in the slightest degree applying it to the present distinguished occupant of the chair, namely, the extreme difficulty, without causing a scandal, of removing an inefficient or undesirable President.

A third inconvenience consists in the tendency towards an unduly Conservative policy, which a permanent President is liable to betray; and a fourth disadvantage is, that the particular department of Science to which the President is devoted is apt to be kept too continuously prominent. These tendencies are opposed to the vigorous progress and the wide expansion of scientific thought which it is the purpose of the Royal Society to foster.

We have but lightly touched upon the salient features of the question, which is one admitting of a vast variety of opinions, some of which, we trust, will be elicited by our remarks, for the appearance of which in these columns we feel that no apology is necessary.*

THE GEOLOGY OF THE DIAMOND FIELDS OF SOUTH AFRICA

IN the September number of the *Cape Monthly Magazine* is an interesting article on the above subject, by Dr. John Shaw, Gold Medallist in Geology at Glasgow University, from which we have made the following extracts:—

"In February 1869, I published a paper in the *Grahamstown Journal* on the geological structure of the Vaal Region along the line where diamonds were found. This was chiefly intended as a reply to Mr. Gregory's denial of the veritability of the discovery of diamonds on various grounds, mainly geological and mineralogical, after a journey of exploration in the region.

"Since that time the finds of surface diamonds have increased, the stretch of country supposed to be diamondiferous has extended, and, at the present time, systematic digging and washing for diamonds are being carried on with an enthusiasm which success alone can have created, by upwards of 1,000 white men in different parts of the Vaal Region, but principally at Klipdrift, near Poreil.

"In July of this year I made considerable observations in the Vaal Valley, which show that the rocks are chiefly trappean, metamorphic, and conglomerate in character. I detected no pure granite formation, but syenite is, however, developed extensively, and seems to be the base of the whole system of rocks at Klipdrift. A very singular rock appears in the shape of isolated boulders on the summits of the Kopjes, and especially of the celebrated Old Kopje. This I take to be graphic granite (binary granite), or what Dana would call 'granilite,' consisting solely of quartz and large crystals of felspar.

"Above the syenite is a trap conglomerate in some places, in others are amygdaloids, and protruding through these again, basalt, assuming everywhere the hexagonal structure, and arising in some places into insulated and compacted columns.

"In some of the Kopjes there are remains of stratified rocks—clay schists, sandstone, chalk (or something very like it), which are evidently the last vestiges of a vast series of sedimentary strata, which formerly covered the whole present contour, but which have gradually given way to denudation and cataclysm.

"Such is the character of the present rock system at Klipdrift, and with a few additions (mainly supercumbent) of the whole rock series of the Vaal region.

"On the summits of the Kopjes, and as a matter of course, in the crevices between the basaltic boulders, is an alluvial gravel. In this are found the diamonds, and on the surface some have been found, indicators of the wealth beneath. The pebbles of sandstone, quartzite,

* The foregoing article, received from a valued contributor, is of so much importance that we have given it this prominence without committing ourselves to an approval of the precise course proposed; we rather invite discussion.—Ed.

crystalline sandstone, granite, clayslate, agate, tourmaline, iron pyrites, garnet, garnet spinel, &c., which compose this alluvium, are all roundedly polished and waterworn, and are imbedded at Klipdrift in a brownish, fatty earth.

"The question arises, Is this alluvium of recent or ancient formation? Did the majority of the pebbles exist in the form of a conglomerate, aggregated from the alluvium of a former age? Or have the Kopjes at no very late period been the bed of the river?

"It is my opinion that the water-worn gravel has been under the influences of running water prior to the last great changes which formed the present landscape. The greater number of the water-worn pebbles and boulders are of the basalt of the Kopjes. Many of them are a crystalline sandstone, others are water-worn fragments of clayslate, sandstone, &c., of the sedimentary rocks which exist in the Kopjes. The agates, tourmalines, and garnets are undoubtedly from some supercumbent conglomerate sandstone which has yielded to denudation and no longer exists at Klipdrift, and also to a considerable extent from the amygdaloidal trap everywhere prevalent. I have in my possession from the Vaal a single fragment of red sandstone containing garnets, but I have not succeeded in tracing this to its source.

"It will, therefore, be sufficiently apparent that there must have existed, at a remote geological period, a series of metamorphic and sedimentary rocks which lay above the present rock system of the region, and that, through successive disturbances and persistent denudation, these have been worn away, forming in great part the alluvial soil of the present surface. In some few spots remnants of this series still exist, as in the clay-slaty crystalline sandstone and conglomerate of Sitlacomies Valley, in the thin layers of claystone, sandstone, and micaceous sandstone of some of the Kopjes now worked for diamonds, and generally in the fragments of sedimentary rocks scattered over the surface along the whole Vaal Valley.

"I am decidedly inclined to think that the diamonds have not been washed down from some higher region. I hope to show in another article that the Free State possesses an independent diamondiferous centre, and that there no river has existed at any time, for there is no evidence of water-wearing, and the soil is not alluvial. Diamonds have been discovered two hours' distance from Potchefstroom, and all down the Vaal to its junction with the Orange River, and thence to ten hours' distance below Hope Town. This is a stretch of at least 500 miles. I believe the diamonds have come from some rock which may now have vanished, but which existed formerly throughout the whole region.

"In concluding at present, I have to make some observations on the position of the gravelly soil which is now being washed for diamonds. The old diggers are in favour of the summits of the Kopjes. They have tested this belief, or rather formed it, from their experience of the old Kopje. How can it be explained that the soil is alluvial and yet deposited far above the influences of the river? For two or three miles inland, which I investigated, there is everywhere on the heights the same deposit.

"There are certain facts which enable me to point out the geological history of these Kopjes. The summits are all basalt. This has been protruded through the amygdaloidal and conglomerate traps. At a subsequent period, however, there must have been another elevation for the blocks and columns radiate from a centre, so that the crevices are wedge-shaped, or expanding outwards to the surface. This subsequent upheaval was evidently not simultaneous throughout the whole region, but successive, and therefore the bed of the stream was changed from place to place. The present bed of the Vaal cannot be an old one, and the whole surface of the country as far as the alluvial soil extends was, at different previous times, under the wearing and breaking influence of the river. Granting, then, a series of rocks such as have been described undergoing water-wearing by the ancient Vaal, which by intermittent and successive upheavals was compelled continually to change its course, and the presence of alluvial gravel on the summits of the Kopjes far and wide is easily explained.

"In the hollows no gravel is apparent, because a thick covering of sand, the accumulation of present denudation, lies over the gravel. Diggers do not care to undertake the labour of carrying off the surface sand at present. In time this will be done, and I am convinced there will be found more diamonds than on the Kopjes And when the day comes when the bed of the stream shall be searched by deflecting the water in canals through the many flats which abound in the Valley of the Vaal, a superior diamondiferous gravel will be worked. From all I saw and for the reason I have now advanced, the present diamond digging of South Africa is only trifling in comparison to what it should and will ultimately be."

THE QUARTERLY WEATHER REPORT

Quarterly Weather Report of the Meteorological Office, with Pressure and Temperature Tables for the Year 1869. Part I. January—March, 1869.

IT is an arduous undertaking to establish and work a system which shall give us a perfectly full, trustworthy, and continuous account of the meteorology of even so small a part of the globe as the British Isles. The Meteorological Committee of the Royal Society are therefore deserving of credit in the systematic effort which they have made to establish the weather records of these isles upon a scientific foundation. Nor must we forget that our Government has been very liberal in this matter, and that a grant of 10,000*l.* a year devoted to meteorology represents a very handsome contribution from that national purse which is, alas! so often shut when it ought to be open, and so often open when it ought to be shut.

Let us now consider how far the Committee have succeeded in advancing our knowledge of British Meteorology, and in what respect, if any, they have fallen short o that which they might have been expected to accomplish. For this purpose let us divide the labours of the Committee into three heads, and consider separately their system of obtaining information, their system of discussing it, and, in the last place, their system of publication.

In the first place, and with respect to their observational system, it is hardly necessary to state that they have established seven observatories in which the various meteorological elements are registered continuously by means of photography, or that the Kew Observatory has undertaken to examine the records from these various outlying observatories before they are sent to the central office. Nor is it necessary to detail the other steps which have from time to time been taken by the Meteorological Committee to insure instrumental and observational accuracy; for men of science have only to examine the various publications of the office to be convinced that a large amount of accuracy has been already achieved.

In addition to the observations from self-registering instruments, other records of a less complete nature come to the office in continually-increasing quantity; for, evidently, the records from only seven stations, however completely equipped, are insufficient to give us a true view of the very complicated meteorology of these isles. It is, therefore, an important duty of the chief officer of the Committee so to increase this stock of observations as to obtain in time a complete and trustworthy meteorological record. There seems reason to believe that this will ultimately be done, and it will be a great boon to meteorological science when it is accomplished.

But, if the observational system is important, the method of reducing observations is a point of equal importance. The condensed account of the quarter's weather, and of its easterly storms, by Mr. Scott, are exceedingly useful summaries, and form, as it were, the first step of the ladder which leads from facts to laws, and it is hardly necessary to state that such summaries have a practical as well as a theoretical importance.

We pass on from these to consider next the tables of averages for the year 1869, which have been given in this Quarterly Report. As far as the air-temperature and pressure are concerned, there can be no objection to tables giving average results. These are two meteorological elements of a nature sufficiently simple to render averaging desirable; and the five-day means of those elements given in page 41 form, perhaps, the best way of accomplishing this. But surely the readings of the wet-bulb thermometer do not represent any simple meteorological element! The moisture is best represented by ascertaining the mass of vapour present in a cubic foot of air, this forming its legitimate expression in terms of *mass* and *volume*, which are fundamental physical conceptions. On the other hand, the temperature of the wet bulb, while it forms the easiest and best observational method of obtaining continuous information regarding moisture, is yet in reality a very complicated joint function of the temperature of the air, of its pressure, and of the mass of vapour present in one cubic foot. To give five-day readings of the wet-bulb thermometer cannot, therefore, we think, lead to any good result.

We are just beginning to know a little about the motions of the atmosphere and its variable components, and if we wish to extend our knowledge in this direction, it seems perfectly essential that the physical meteorologist should choose proper methods of reduction. His method ought not to be one which, when accomplished, *may possibly* increase our knowledge, but one which, from its very nature, *must necessarily* do so. He ought to seek to have the same certainty which the astronomer possesses, that in treating his observations after a particular method, the results will infallibly extend his knowledge of celestial motions.

We have dwelt so long upon this part of the labours of the Meteorological Committee, that we can only briefly allude to their system of publication. The reduced graphical representations of the observatory records given at the end of the volume, while hardly enough for the wants of meteorologists, are yet extremely valuable and useful. It is impossible to say what benefit to science may not result from bringing before the public such a speaking epitome of weather, and we owe many thanks to Mr. Francis Galton, the member of the Meteorological Committee who invented the instrument which has given us these admirable plates.

BALFOUR STEWART

BEET-ROOT SUGAR

On the Manufacture of Beet-Root Sugar in England and Ireland. By William Crookes, F.R.S., &c., Editor of the *Chemical News.* Illustrated with ten engravings. Pp. 290. (London: Longmans, 1870.)

THIS work is founded on a series of articles by M. Julien M. Deby, C.E., published about a year ago in the *Scientific American;* these articles have, however been very much extended, and much new matter added, in order to bring the subject down to the present date, and so increase its usefulness in assisting those who may wish to establish beet-root farms and sugar factories in this country. The experiences obtained abroad, and investigations made in England and Ireland, show that it would be quite possible to grow sugar-beets with profit in the United Kingdom. The beets might be used as fallow crop and cultivated, instead of the roots grown in such great quantities as food for cattle, since the beet-root pulp after the extraction of sugar is even more valuable for this purpose.

During the year 1867, beet-root sugar of the value of 1,600,000*l.* was imported into this country, and it would appear that this might readily have been produced here. In the first chapter we have a description of the beet, and of the qualities that can most profitably be used for sugar making; the weight of each root should not be less than 1¼lb., nor more than 2lbs.; smaller roots are frequently woody, while larger ones are watery and poor in sugar. The juice should have a specific gravity between 1·060 and 1·070, though sometimes, when very rich in sugar, it rises to 1·075 or 1·078. The percentage of sugar in the roots varies considerably, the minimum quantity given in a long list of analyses being 3·62, while the maximum is 13·47. The next number below this maximum is 13·19, and is interesting as representing the amount of sugar found in red beet manured with London sewage. Peligot obtained as much as 18 per cent. from some French beets, and some American specimens have produced 17·6 per cent. It has been found in Ireland that from 16 to 40 tons of roots may be grown on one acre, so that satisfactory results might be anticipated in that country. Chapter II. treats of the culture of the beet, the climate, kinds of soil, manure, and all the necessary directions to the agriculturist to ensure a profitable return. Chapters III. to VII. contain a detailed description of the mode of extraction of the sugar, and a very useful statement of the cost of the different pieces of apparatus required for working up 150,000lbs. of beet-root per twenty-four hours during five months, which would be the average yield of a 500 acre farm. Chapter VIII. gives the quantity of water required in such a factory, amounting to no less than 113,190lb., or 1,882 cubic feet per hour; the expense of labour for one year at 5,190*l*., the total annual expense being 13,980*l*., the total receipts being estimated at 20,470*l*., leaving a profit of 6,490*l*., assuming that 8 per cent. of sugar is extracted from the roots. It is however probable that this percentage might be raised to 10 per cent., when the profit would be 10,090*l*. The first outlay for the establishment of the factory is calculated at 10,845*l*. Mr. Baruchson estimates the profit at 24¾ per cent. on the outlay when 6½ per cent. of sugar is produced, each additional ½ per cent. increasing the profit 7½ per cent., so that if 8 per cent. could be obtained the profit would be no less than 48 per cent. The ninth chapter describes the concreting process of Mr. Fryer as applied to the raw juice, so as to enable the refinery to be carried on during the whole year instead of only during crop time. Chapter X. is devoted to the application of the spent beet-root pulp. As far as chemical analysis indicates it will prove, when mixed with other materials, a more useful food for cattle than ordinary mangolds or even than the original roots, though it must be admitted that no comparative experiments on feeding have yet been made. The remaining five chapters describe the manufacture of spirit from beet juice, which has been found very profitable on the Continent; the sucrate of lime process which dispenses with the employment of animal charcoal; the manufacture of potash salts from the residues; Excise regulations, and Dr. Schiebler's calcimeter for the determination of the quantity of carbonate of lime in animal charcoal.

We commend this valuable work to all interested in the subject; and wish the author success in his endeavours to introduce and encourage the extensive cultivation of beet-root in this country, and thus place us on a level with our neighbours on the Continent who have so successfully carried it out.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.]

Dr. Balfour Stewart's Opening Lecture at Owens College, Manchester

DR. BALFOUR STEWART concludes his excellent Lecture lately delivered at Owens College, Manchester, and published in your number for Oct. 20th, with a broad classification of experimental and observational work into work requiring much time and work requiring comparatively little time for its execution. This appears to me a very useful suggestion. Dr. Stewart then goes on to say that the work requiring short periods of time "may be furthered with much advantage in institutions such as Owens College." And he adds that the same objects are at present aided by the Government grant of 1,000*l*. so carefully administered by the Royal Society; but he thinks this grant might be advantageously increased. In all this I quite agree with him.

Dr. Stewart then proceeds to deal with the other class of scientific work. And here I had better quote his own words. He says:—"But when we come to experiments and observations re-requiring great time, the case is very different. Certain experiments, whether from the great time they require, or the great expense they demand, cannot be well performed in a College; while routine and long-continued observations, such as those connected with the various branches of cosmical physics, are of such a nature as to require a central establishment to superintend their organisation and reduction. There is thus, I think, the necessity for a central establishment of some kind, devoted to that class of experiments and observations requiring great time, great space, and great expense for their completion."

In every word of this also I agree with Dr. Stewart. But I think a few words more are wanted to tell us by whom or how these institutions should be founded and supported. I, who have had the advantage of very frequently discussing the question with my friend Dr. Stewart, infer, without any hesitation, that he considers this should devolve on the State, which, as I have often stated in public, is my own opinion. But I think it a pity that, at a time when the question is attracting in scientific circles so much attention, this should have been left to inference by one so well qualified to speak with authority, and on an occasion which afforded so excellent an opportunity of educating public opinion, on a subject which, outside scientific circles, is so little understood.

ALEX. STRANGE, Lt.-Col.

The Aurora Borealis

A PRETTY bright display of the aurora, which was witnessed here last evening, exhibited such peculiar phenomena, that although I am told that they are common accompaniments of the aurora here, a description of them may yet be new to some of your readers. The times given in the description are by estimation from the striking of town clocks; the night being dark, and the light of the aurora not sufficient to enable me to consult a watch.

At $8^h\ 25^m$ a straight double beam of faint white light extended from Altair in the west, across γ Andromedæ overhead, nearly to the E.N.E. horizon. The northern branch of the arch was the brightest, about 3° broad, and it was accompanied at a distance of 10° or 12° on the southern side by a parallel and fainter arch. I was prevented from watching the duration of this appearance and the further progress of the aurora until a few minutes after ten o'clock. At that time a few columnar streamers of white were visible in the west, one of which, very bright, extended from α Sagittæ to ζ Cygni, and was accompanied by fainter streamers from β to between γ and ϵ Cygni, and from Altair to δ Cygni. I noted their direction, and that of a few other streamers later, in opposite parts of the sky, in order to determine the position of their centre of convergence. But this was at the same time clearly shown by a patch of nebulous white light, 10° or 15° wide, from the centre of which, at β Andromedæ, and to some distance beyond its borders, faint rays spread outwards, and mixed themselves with faint streamers which rose in close array, from the north and east, towards them. While watching this small light-cloud, its light and that of the surrounding streamers became rapidly and brightly intermittent. It soon faded, and on reaching an eminence where I could command the whole northern sky from east to west, I found that all the features of the aurora were undergoing very rapid changes. Two of the many broad and bright streamers which rose in that direction at about $10^h\ 25^m$ were directed from β Ursæ minoris to γ Cephei, and from θ Aurigæ to Algol, having their bases at the former stars, and connected, apparently, by no regular fringe or arch below, but appearing at different heights between the zenith and the horizon, and occupying chiefly the north-west to north-east quarter of the sky. The full extent of the intermittent phase, of which I had before obtained only a confined and obstructed view, was now also visible. Waves of light coursed each other over the whole extent of the streamers in no very regular direction or succession, but so as to give the general impression that conflicting currents of air, chiefly from the north, blew out and carried along with them the light of the streamers towards their highest points, or from one streamer to another. Hardly more than a second was occupied by the waves in spreading from the horizon to the zenith; and in their number, appearing simultaneously, they appeared to vary from a quick succession of ripples to a single wave. This agitation of the streamers subsided at about $10^h\ 30^m$. The centre of convergence of the streamers between β and γ Andromedæ was variously marked at about this time by a faint corona, without enclosed light, or by a nebulous light-cloud composed of irregularly radiating beams. It was traversed, apparently, by the waves from the north, east, and west, as rapidly as other portions of the sky; and but little indications of the aurora were visible to the southward from this point. For a space of about ten minutes the aurora appeared to be fading, but at about 10^h 40^m a bright streamer, 5° or 6° broad at its base, rose upwards from the "pointers" to above the Polar star, while the whole northern half of the sky was again covered with fainter streamers. Waves of light flashed rapidly along the principal beam, from its base to near the zenith in about one second, and at the same time drifted upwards over the other parts of the aurora in extremely vivid and rapid succession. The progress of the disturbance continued the same, and was watched for about ten minutes, during which time occasional bright streamers rose and faded, and all the beams of the aurora were equally lighted up by the flitting waves. The motion of the latter appeared to be in parallel lines rising upwards from the N.N.E. horizon, and where in that direction the bases, or brightest parts, of the streamers were arranged in a continuous succession of altitudes from near the horizon to the zenith, the waves appeared to be propagated in the most regular and unbroken manner. Tall streamers at a considerable distance east or west of the magnetic north were lighted up very rapidly from their bases to their summits, as if directly confronted throughout their whole lengths by the advancing waves. At about 10^h 45^m, the cloud-like apex of the aurora was somewhat nearer to γ than to β Andromedæ, and it was lighted up like the occasional tall streamers in the east and west, by almost momentary flashes of pale, phosphorescent light. The impressions of a luminous vapour, like that which floats over phosphorus, of the *ignis fatuus*, or of the disturbed surface of a phosphorescent sea, blown by the wind, were most vividly suggested by the flickering changes of brightness in portions of the auroral cloud overhead. At 10^h 50^m the disturbance ceased, and the streamers gradually resumed their steadiness, some appearing soon afterwards in the south-west, from between θ Pegasi and α Aquarii to α Pegasi; and others, in the south-east, across Aries and Taurus. The auroral apex was faintly visible, at this time, near γ Andromedæ. At about 11^h, a third disturbance among the auroral beams occurred for a few minutes overhead. A slightly curved arch 2° or 3° broad, extending towards the east and west about 20° on each of the apex, and lancelike streamers in the east and west, which, together with the arch, were in their ordinary state invisible, were repeatedly lighted up suddenly and very brightly, and were immediately again extinguished; the light sometimes appearing in the beams and sometimes in the arch, as if it were bandied to and fro between them. The streamers in the north were at this time very faint, and those in the south-east and south-west were almost entirely hidden by clouds, which a rising wind now drove across them from the south. From 11^h 8^m to 11^h 10^m a rapid succession of horizontal waves and wavelets of light rose in parallel lines above the N.N.E. horizon, drifting, apparently, overhead towards the south. As they appeared to catch the beams, and the arch which still remained extended across the apex towards the east and west, these were suddenly lighted up, and immediately again extinguished, as before; the flickering and dancing effect of the light which they produced resembling that reflected on the clouds in the south from distant iron-smelting furnaces upon the opposite bank of the Clyde. A repetition of the flashing lights, which, I presume, must have been those described by ancient writers as *capræ saltantes*, and by mariners familiar with displays of the aurora in high latitudes as "merry-dancers," occurred again among the beams overhead between 11^h 12^m and 11^h 14^m. Soon after this, thick clouds came over from the south, and the sky very shortly afterwards became overcast.

The beams of this aurora were uniformly white, without any trace of colour. But the farthest east and western beams of a bright aurora seen here from 8^h to 11^h on the evening of Thursday last, the 20th inst., were of a rich crimson red, and one tall streamer of that aurora, reaching nearly to the zenith, exactly in the north, was tinged with crimson at the top. A south-west wind, occompanied by rain, succeeded that aurora on the following day. Last night a south-west gale sprang up, and there was a considerable fall of rain here this afternoon. I heard no crackling sounds during the brightest flashing of this aurora; but such sounds might very possibly be produced in Arctic regions by the cracking of ice, which great pressure, or a change of temperature in a gale of wind, would be not unlikely to occasion as a concomitant of the aurora, if, as was recently suggested by the late Admiral Fitzroy, auroral displays in these latitudes accompany, and are pretty certain indications of the existence of, very stormy weather at a distance. A. S. HERSCHEL

Andersonian University, Glasgow, Oct. 26

A WONDERFULLY fine auroral display took place last night, very far exceeding in extent and brilliancy that of the 24th ult., as seen from this place. It began to show itself soon after sundown, attained its maximum about 8 o'clock, and had not wholly disappeared at 11. At about 8 o'clock more than half the visible heavens was one sea of colour, the general ground greenish, yellow, and pale rose, with extensive shoals of deep rose in the east and west, and from the north; streaming upwards to and beyond the zenith, tongues and brushes of rosy red so deep that the sky between looked black. The spectroscope, a direct-vision one, showed four lines in the rosy portion and one in the greenish; one strong red line near the C, one strong pale yellow line near the D, one paler near the F, and one still paler beyond, with a faint continuous spectrum from about the D to beyond the F. The C line was very conspicuous and the brightest of the whole, intermediate in position and colour to the red of the lithium and the calcium, with both of which I am familiar; plainly there were two spectra superposed, for while the red portions of the aurora showed the four lines with a faint continuous spectrum, the greenish showed only one, near the D on a faint ground. Of course, no numerical accuracy was attainable with so simple an instrument, only the judgment of the eye; but the conviction was very strong that the rosy hue was owing to hydrogen, possibly resulting from decomposition by electrical discharges of the excessively attenuated watery vapour existing in the higher regions of the earth's atmosphere, which Tyndall has shown to be capable of producing the blue colour of the sky, and by the consequent loss of which the blackness of space was discernible. T. F.

St. Mary Church, Torquay, Oct. 25

SHORTLY after sunset this evening an ill-defined auroral arch was seen in the north. At about 7·45 patches of rose-coloured light were visible about the constellations Auriga, Ursa Minor, Ursa Major, &c., and at about 8 o'clock brilliant crimson rays shot up to the zenith, and the sky seemed one vast mass of fire. The auroral light was visible as far south as Cetus and Aquarius. The crimson tint passed from time to time into a greyish light.

When the most brilliant portions were examined with the spectroscope, two bright lines were visible, one a greenish-grey line situated about the middle of the spectrum, and the other a red line looking very much like the C hydrogen line.

London, Oct. 24 W. B. GIBBS

DURING the recent brilliant auroral displays (Oct. 24th and 25th), I observed four bright lines in the spectrum of the crimson beams of the corona.

1. A broad and well defined red band near C.
2. A bright white band near D (? the same as Angström's line with wave-length = 5567). I have frequently seen this line even during very faint displays; on the 25th it was visible in every part of the sky.
3. A faint and rather nebulous line, roughly estimated to be near F.
4. A very faint line about half way between 2 and 3.

The red band was absent from the spectrum of the white rays of the aurora, but the other lines were seen.

Bedford, Oct. 29 THOS. G. ELGER

ON the night of the 25th a most gorgeous aurora borealis was visible at North Shields. I first observed it about 6 P.M., when it formed a splendid boreal crown, of which the centre was about 25° south-east of the zenith. Rays of brilliant crimson converged to it from all directions, especially from N.E., S., and S.W. To the north the light was more of the ordinary colour. They appeared to rise from an irregular circle, extending round the whole horizon, and slightly arched in the N.W. Below this was the usual dusky cloud. When the rays, or rather sheets, of crimson were at their brightest, they were streaked with yellowish light. At times the centre of convergence was dark, at others it was occupied by luminous clouds of twisted forms, reminding me of those of some of the nebulæ. The rays seemed to have a slow motion towards the south.

About eight o'clock the crown gradually faded, and the light of the centre flickered with a tremulous motion. At 8.15 an arch shot across the sky from N.E. to S.W., passing just north of the pole star. It slowly drifted south, and at 8.30 was in the zenith. At 10 the boreal crown had reappeared, but was of the ordinary yellowish colour.

The spectrum of the red rays contained a brilliant red line, more refrangible than Hα, in addition to those usually seen. It was situated about ·4 of the distance from C to D. If any other observer noted the position of the arch observed at 8.15 P.M., I shall be glad to be informed, in order to calculate the height.

Clementhorpe, N. Shields, Oct. 27 HENRY R. PROCTOR

ANOTHER display of aurora borealis occurred this evening. It was not to be compared in splendour with that of the night preceding, but it had some interesting and instructive features. The sky was not clear at any time, and the masses of red light, which occupied generally similar situations to those of the preceding night, were interrupted in many places by dense clouds. I observed it at about half-past six P.M., and at that time the most remarkable feature was that streamers (generally not of a red colour) radiated from every part of the north horizon accurately to a point defined very nearly by one of the stars σ Cygni or υ Cygni, which were then near the meridian. I did not see both stars, and I am therefore in doubt, as they are of equal magnitudes, which was the star nearest to the point of convergence of the streamers.

The radiations were so well marked and so accurately directed to one point, that I mentally compared them to the ribs of an expanded umbrella. This did not last long; in a few minutes fine streamers went from the N.W. horizon towards the south-east, to the east of this point, which was then covered with red light without streamers. The largest masses of red light were, as in the preceding evening, south of the zenith, and in the south-east and south-west quarters of the heavens.

Radcliffe Observatory, Oxford, Oct. 25 ROBERT MAIN

A MAGNIFICENT auroral display was visible here on the evening of the 24th, between $8^h\ 0^m$ and $8^h\ 30^m$.

The maximum of intensity must have occurred between $8^h\ 0^m$ and $8^h\ 20^m$, but, being otherwise engaged, I did not observe anything myself until $8^h\ 25^m$, when the E. and W. regions of the sky, more especially the latter, were illuminated with a crimson or reddish glow, somewhat resembling the reflection of distant conflagrations, but on neither side did this glow appear to reach the zenith by many degrees. Shortly after the time mentioned ($8^h\ 25^m$) both disappeared, after which a phosphorescent whitish light was observed nearer to and on the S.E. of the zenith. The barometer had, during the previous day or two, shown considerable variation in atmospheric pressure.

Another display was observed on the following evening (25th), which commenced about $6^h\ 0^m$ and continued visible more or less until $7^h\ 0^m$.

The first indication that I noticed was a fiery glow similar to that seen on the previous evening, but considerably higher, and almost immediately after a magnificent broad stream of light, consisting of reddish and light tints, was observed in the N.E. extending upwards for 50° or 60°.

About $6^h\ 20^m$ the whole of the northern region of the sky extending to E. and W., and about 15° S. of the zenith, was more or less illuminated, and I should say the maximum of intensity occurred at this time. The principal luminous streams and coruscations appeared between N.E. and E.N.E. appearing first in the latter direction and increasing towards the former.

On one occasion I noticed faint luminous streamers rising from different northerly directions and converging in the zenith; these, together with the coloured bands of light before mentioned, formed a magnificent and imposing spectacle.

The northern sky afterwards presented an appearance of twilight until about $10^h\ 45^m$.

During the display the barometer stood at 29·53 (corrected for temperature). Temperature of air 49°. The minimum temperature registered during the night was 42°.

Meteorological Observatory, Twickenham JOHN J. HALL

COLLINS, in his "Superstitions of the Highlands" has these lines:—

As Boreas threw his young Aurora forth
In the first year of the first George's reign,
And battles raged in welkin of the North,
They mourned in air, fell, fell rebellion slain!

The Editor (Routledge's edition) in a note states "By 'young Aurora' Collins undoubtedly means the first appearance of the Northern Lights, which happened about the year 1715; at least it is highly probable from the peculiar circumstance that no ancient writer had taken any notice of them, nor even any modern previous to the above date." Can any of your readers state whether this is correct. C. POCKLINGTON

Poole, Oct. 27

AN aurora borealis was visible at this place on the evening of the 25th inst., between the hours of 7 and 8.30 P.M. A beautiful crimson glow was first observed towards the north-east, veiling, but not hiding, the larger stars, and the Pleiades had the appearance of a wedge of pale yellow mist behind the veil. On the horizon, looking due north, was a semicircular luminous space of clear pale light, of the colour of eastern sky just before dawn, and from this there darted at intervals over the crimson glow long slender rays of yellowish light, giving an exceedingly beautiful appearance to the phenomenon. Clouds, which had been hanging about during the day, gathered over the scene towards 9 o'clock, and when they afterwards dispersed before midnight, the glow, though still perceptible, was fading away. A falling star was observed at about eight, but considerably to the south of the aurora. There had been an aurora observed on the preceding evening, but of a less striking character. The weather has been for the last ten days extremely unsettled, sirocco (S.E.) winds prevailing, and an unusual rainfall the result, accompanied sometimes by hail, and by thunder and lightning. But clear bright days occur in the intervals of these storms, when the sky is of an intense blue, against which beautiful forms of cloud mass themselves by degrees as the day goes on, and become at length the subjects of those gorgeous atmospheric effects which make the autumnal sunsets of the bay of Fiume rivals of those of Rome.

Fiume, Oct. 28 A. M. SMITH

[In addition to the letters printed above, we have received from many other correspondents interesting and valuable descriptions of the magnificent display of the aurora, which the demands of other subjects on our space alone prevent us from publishing.—ED.]

The Aurora of Sept. 24

IT may interest your readers to know that the very brilliant aurora of the 24th and 25th September last was also visible in Canada. Mr. W. B. Dawson, writing from Montreal, notices the occurrence of a very bright aurora on both nights, flashing much, and often bright crimson. It was also seen at Quebec, and attracted much attention. He observes that its appearance was simultaneous with the division of a very large spot on the sun. Its crimson colour agrees with the red hue of your other correspondents; and is somewhat remarkable, as I have often noticed, in Canada, that the red usually alternates with green in vivid displays. GEORGE M. DAWSON

Royal School of Mines

Hereditary Deformities

THE alleged instances of hereditary deformity produced by your correspondent in NATURE for Oct. 20 do not seem at all satisfactory. They may all be referred either to an hereditary disease of the part affected, as in the suppuration of the cow's horn; or to coincidence, accompanied by a slight stretch of imagination on the part of the first narrator, as in the cases of the scar on the forehead and the crooked finger.

Prof. Huxley, in his lectures on Natural History at the Royal School of Mines in 1864, after speaking of the short-legged breed of Ancon sheep, and the six-fingered Maltese, Gratio Kelleia, said that although natural malformations were thus transmitted, artificial malformations never were; and instanced the fact of the mutilation produced by circumcision never being transmitted to the offspring. This, of course, is a negative argument, but it has great weight when we consider how many thousands have undergone that mutilation without an instance of its having been inherited by their children.

Faversham, Kent, Oct. 25 WILLIAM FIELD

The Cefn Reptile and the "Times"

THE remarkable paragraph in the *Times* of the week before last relating to the discovery of "a huge beast of the lizard tribe," in a cave at Cefn near St. Asaph, implies a belief on the part of the editorial staff that such an addition to the British fauna was not impossible, and its wide circulation proves the astonishing credulity of the public:—

"In the Vale of Clwyd, at a distance of two miles from the cathedral city of St. Asaph, are situated the Cefn Caves. It had been rumoured of late that parties visiting this place had on several occasions seen some strange animal creeping in its dark recesses, and on Saturday visitors reported having had a good view of him, and stated it was a huge beast of the lizard tribe. On the Monday following Thomas Hughes, from Rhyl, went to try to capture him. Armed with a stout stick he approached its reported lair, but not seeing it he decided to remain in ambush at the mouth of the cave, sheltered by a projecting ledge. After having thus waited an hour his patience was rewarded with success. He could hear in the far end a hum as of a hive of bees. The sound growing louder, and now apparently quite close, Hughes peeped round the ledge, and saw the monster within three yards of him. He (Hughes) sprang towards him, and dexterously wielding his stick he dealt him a well-aimed blow upon the neck just behind the head, which caused him to stagger and reel. One more blow in the abdomen finished him: Hughes carried him home in triumph, and is now making a profit out of the affair by exhibiting him at Rhyl. The monster is of the lizard tribe, as mentioned above. Only that our country is destitute of those creatures we should have said it was a young crocodile. It measures from the nose to the end of its tail exactly 4ft. 7in., the tail being rather more than half that length. Its limbs measure 12in.; the front ones have five toes; and the hind ones four; it is webfooted. Above it is black and white beneath. Its coat is mailed, quite hard, and protruding in sharp corners and angles, like the crocodile's. The head is low and flat, the mouth large and round at the end, measuring 7in. by 3in.; the teeth are numerous, but small, and bear great resemblance to those of a large codfish. There is ample scope here for naturalists to investigate the how and wherefore this strange amphibian came to be discovered in the present epoch among the hills of North Wales."

Such is the vivid account of the capture given in the *Times*, and reprinted in several local papers; and so far as I can judge by my letters, believed in by many simple-minded people. It is altogether a most impudent hoax. The man Hughes is a sweep, who purchased a reptile which happened to die in a travelling menagerie at St. Asaph, and exhibited it at Rhyl as having been caught in the Cefn Caves, until at last it became a public nuisance, and was committed to the earth. The story related in the *Times* was invented merely to make the exhibition lucrative to Hughes the sweep. Its wide circulation, which incidentally shows an astonishing ignorance of natural history, is the only excuse for my writing this letter.

W. BOYD DAWKINS

MAN AND NATURAL SELECTION

THE following reply to M. Claparède's "Remarques à propos de l'ouvrage de M. Alfred Russel Wallace sur la Théorie de la Sélection Naturelle," was written some months ago, and was intended as an appendix to a French translation of my "Essays" by M. Lucien De Candolle, to be published by Reinwald, of Paris. As it is now very uncertain when the translation will appear, and as M. Claparède's critique has been highly spoken of in several English periodicals, I think it advisable that my answer to it should be no longer delayed.

In the "Archives des Sciences de la Bibliothèque Universelle," for June, 1870, M. Edouard Claparède has done me the honour to make my "Contributions to the Theory of Natural Selection" the subject of some critical remarks. To these I now propose briefly to reply.

I must premise that I do not intend to discuss here any of those difficulties which my critic finds in the theory of sexual selection, and which apply as much to Mr. Darwin's views as to my own, because, in his new work now announced, that theory will, I have no doubt, be fully developed, and be supported by a mass of facts and observations, in the absence of which further argument is useless. I proceed therefore to the objections that apply more especially to my own views.

At p. 15 of his "Remarques" M. Claparède says, "Son étude est consacrée á la coloration des oiseaux et, absorbé dans son sujet, l'auteur oublie que d'autres facteurs peuvent, aussi bien que la couleur, attirer l'attention des ennemis sur la gent ailée. Un nid couvert d'un dôme volumineux échappera tout aussi peu, grâce à ses dimensions, à l'œil d'un animal en quête de proie, que quelques plumes brillament colorées. Les gamins de nos villages en savent quelque chose, comme l'a remarqué M. le Duc d'Argyll, et ils ne réussissent que trop, à la présence d'un gros nid, à deviner l'oiseau caché et sa couvée." This objection does not seem to me very serious, because in the first place, nests, however large, generally harmonise in colour with surrounding objects, and are not so easily seen at a little distance as a bright patch of colour; and, secondly, because "gamins" are not the chief natural enemies of the feathered tribes, while hawks and falcons do not break open nests, although they do seize and devour birds.

After giving (p. 23—25) what I must allow to be a very fair abstract of my reasons for believing that Natural Selection is not the only power that has operated in the development of man, M. Claparède intimates that I have so completely abandoned my own Darwinist principles that the reader will easily refute my arguments. He therefore confines himself to certain "reflections." I regret that he did not think it necessary to do more than this, because I have as yet in vain sought from my reviewers for any other than general objections to my arguments on this subject, and am at a loss to know how they can be so easily refuted. M. Claparède's "Reflections," however, do, fortunately, take the form of arguments. He says (p. 25), "M. Wallace n'a pas reculé devant l'explication de la formation graduelle du chant de la fauvette et du rossignol par voie de selection naturelle. La chose est toute simple, bien fou serait celui qui voudrait recourir ici à l'intervention d'une Force supérieure, ami du Beau! Les fauvettes femelles et les rossignols de même sexe ont toujours accordé de préférence leur faveurs aux mâles bons chanteurs. C'était la conséquence de leur goûts musicaux et des aptitudes harmoniques de leur oreille. Malheur aux pauvres mâles à registre peu étendu ou à timbre fêlé! les douceurs de la paternité leur ont été impitoyablement refusées; ils sont morts de jalousie dans la tristesse et l'isolement. Ainsi s'ést formée la race des bons chanteurs qui peuplent nos bocages. Pourquoi n'y a-t-il pas des chanteuses? Sans doute que les oiseaux mâles ne se sont jamais souciés de la voix de leurs épouses, soit parcequ'ils n'avaient pas l'oreille juste, soit plûtot, car cela sera contradictoire, parceque leurs gouts musicaux étaient suffisament satisfaits par leurs concerts personels. Peut être aussi les femelles n'avaient-elles point d'aptitude virtuelle au perfectionnement de la voix; peut être avaient-elles atteint l'extrême limite de développement vocal compatible avec l'organisation d'un oiseau du sexe féminin; ou bien enfin la sélection naturelle produite sous l'influence des poursuites exercées par des ennemis de toutes sortes contre les belles couveuses, sélection favorable, selon M. Wallace, à la production de couleurs sombres, a-t-elle mystérieusement éteint même l'éclat de sa voix? Quoiqu'il en soit, il est évident pour M. Wallace que la sélection sexuelle, en d'autres termes le goût des dames fauvettes pour la musique, a amené le grand perfectionnement de la voix des virtuoses de l'autre sexe. Mais dans l'espèce humaine, la chose aurait-elle pu se passer ainsi? Le chant harmonieux et enchanteur d'une *prima donna* aurait-il pu naître et se perfectionner par voie de sélection? Le goût musicale des auditeurs pourrait-il avoir eu une influence selectrice sur ce phénomène? Jamais, au grand jamais! Seule l'intervention d'une Force supérieure a pu amener un résultat pareil, car jamais homme primitif n'a eu de goût pour la musique. M. Wallace le sait bien: il a vécu si longtemps parmi les sauvages qui ont pu le lui dire! Au contraire, les femelles fauvettes primitives et les femelles rossignols primitives, avaient déjà le goût musical longtemps avant que leurs époux eussent appris à chanter.

Comment M. Wallace le sait-il? Le lui ont-elles dit? N'importe, il le sait."

It is a pleasure to read anything so brilliant as this, but it hardly seems to touch the point of my argument. Male birds *do* sing at pairing time to the females. Mr. Darwin says in his "Origin of Species," "All those who have attended to the subject believe that there is the severest rivalry between the males of many species to attract, by singing, the females." Female birds do *not* sing. These are facts, and they perfectly accord with the theory of the perfection of song having been developed, in the *males*, by sexual selection. In man the facts are all different. Savage women have generally no *choice* as to their husbands, as has been so fully shown by Sir John Lubbock; and in the few cases where a choice is open to them, there is not a particle of evidence to show that a musical voice ever determines that choice. Still less reason is there to think that this quality determines the male savage in choosing his wife. Yet a wonderful musical organ has been developed in both sexes, of which the use to man in his struggle for existence has not yet been shown. Surely here is a difficulty which required facts and arguments for its elucidation rather than a brilliant display of wit.

Again, in reply to my arguments as to the total absence of hair from the back of man, we are told that it should be no difficulty to a person who believes that *hairy* mammals and *feathery* birds have been derived from *scaly* reptiles ("Remarques," pp. 27, 28) But surely this is not the argument of a Darwinian. For the hair and the feathers are *useful* to their several possessors, just as the scales were to their ancestral reptiles; whereas the very essence of my difficulty is, that the nudity has *not* been shown to be *useful* to man. M. Claparède thus concludes his remarks on this subject:—"Que M. Wallace soit au moins conséquent dans la question de la chute des poils. Si l'intervention d'une Force supérieure lui semble nécessaire pour épiler le dos de l'homme, qu'il sache se résoudre à la faire agir de même sur l'échine de l'éléphant, du rhinocéros, de l'hippopotame ou du cachalot." But the four mammals here mentioned are *thick skinned* animals, one *aquatic*, one *amphibious*, the other two inhabitants of *hot* countries, lovers of *shade* and of *marshes*. Can anything be more clear than that, in all these cases, the hair was little or not at all wanted, and, owing to their habits, was very probably even injurious, and has therefore partially disappeared by means of natural selection? while the extinct mammoth and woolly rhinoceros are instances which prove that it always re-appeared when the needs of the animal required it. If the hair disappeared from the back of tropical man by the action of the same law which caused it partially to disappear from the tropical elephant, we must ask why it did not re-appear in the arctic Finns and Esquimaux, as it re-appeared in the arctic mammoth? It is rather for me to say—"Que M. Claparède soit au moins conséquent dans la question de la chute des poils."

The last point on which my critic remarks is my argument, that the brain of savage man is in advance of his needs, and therefore could not have been acquired by natural selection; and he asks, why I do not apply the same reasoning to many other cases, especially to that of the great group of birds with a complex larynx, comprising all the singing birds, yet having many species which do not sing. He says (p. 29), "Ces oiseaux possèdent dans leur larynx un organe beaucoup trop bien conformé pour l'usage qu'ils en font. Il est donc nécessaire d'admettre l'intervention d'une Force supérieure pour façonner cet appareil, inutile aux oiseaux qui le possèdent, mais calculé en vue de générations nouvelles qui, dans un avenir plus ou moins éloigné et dans des conditions déterminées apprendront à chanter. Que M. Wallace aurait-il à répondre à une semblable argumentation?" My answer is, that the cases are not parallel or similar; if they were so, I should certainly adopt the same conclusion in both. To make them logically comparable, it would be necessary to prove that all the earlier forms of the group had the vocal organs fully developed, but did not sing; or what might be held to indicate this, that at present only a few species sing, while the great mass do not. But so far from this being the case, the majority of the species of the group have musical or sonorous voices, and there is no evidence to show that the vocal apparatus was fully developed before the power of singing began to be exercised. Man, on the contrary, stands alone in the development of his brain, and M. Claparède does not rebut the evidence I have adduced to show that the brain in savage and prehistoric man was in advance of his requirements.

In concluding his remarks, M. Claparède endeavours to impale me neatly on the horns of a dilemma, as follows:—"Ou bien M. Wallace a eu raison de faire intervenir une Force supérieure pour expliquer la formation des races humaines et guider l'homme dans la voie de la civilisation, et alors il a eu tort de ne pas faire agir cette même force pour produire toutes les autres races et espèces animales ou végétales; ou bien il a eu raison d'expliquer la formation des espèces végétales et animales par la seule voie de la sélection naturelle, et alors il a eu tort de recourir à l'intervention d'une Force supérieure pour rendre compte de la formation des races humaines." These are his last words, and they seem to me to be the weakest in the whole paper, being a pure begging of the question. They assume that man presents no phenomena which differ in kind from those presented by other animals, whereas I have adduced a number of such phenomena which my critic has neither disproved nor denied. My whole argument is founded on certain facts, and on these facts only. My critic admits the facts, does not refute my arguments, yet maintains that I should give up my conclusion, because the theory of Natural Selection *must* apply equally to man and the rest of Nature, or to neither. But why must it do so? Darwin himself claims no such universality for it. He admits that even the common origin of animals and plants rests only on analogy, and that "it is immaterial whether it is accepted or not." But M. Claparède is more Darwinian than Darwin himself, and would, I presume, say that, either all animals or plants must be descended from one common ancestor or, that no two species are thus descended. I maintain, however, that man is descended from a lower animal form, but I adduce facts which go to prove that some other law or power than Natural Selection has specially modified him. If Darwin is not anti-Darwinian in admitting, as he does, the possibility that animals and plants may not have had a common ancestor, I may surely deny that I am anti-Darwinian when I show that there are certain phenomena in the case of man that cannot be wholly explained by the law of Natural Selection.

I must not conclude without thanking M. Claparède for the very flattering terms in which he has spoken of the larger portion of my work, and also for the general accuracy and fairness with which he has condensed my views and arguments in the last essay, to which he especially takes objection. A. R. WALLACE

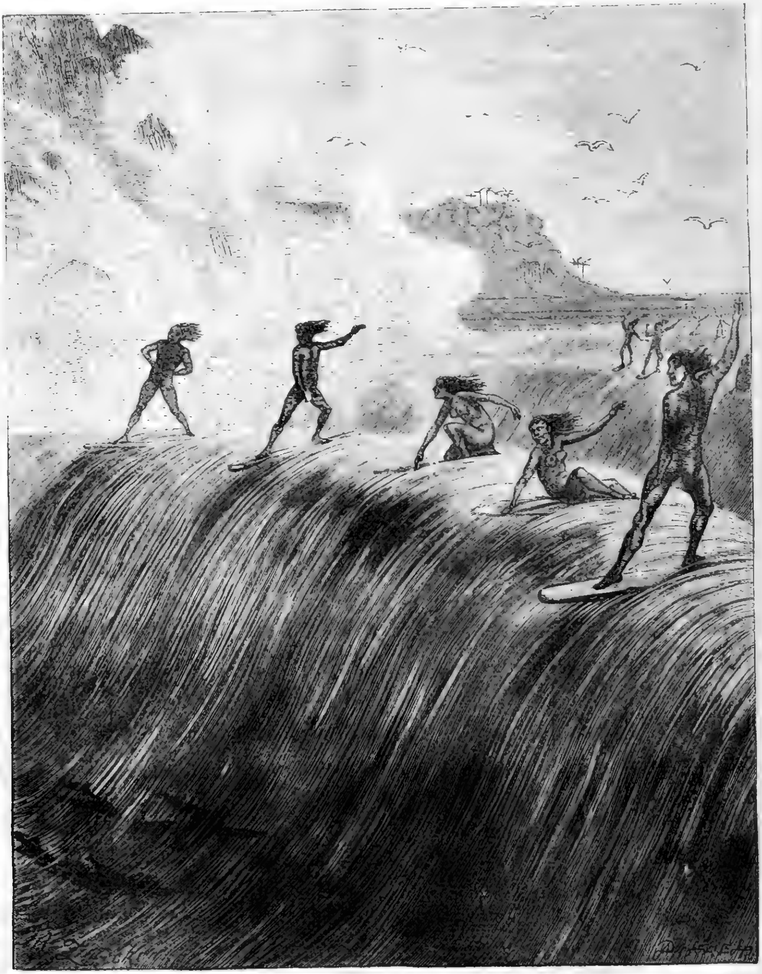
THE NATURAL HISTORY OF MAN*

IN the two handsome volumes before us is contained such a mass of interesting information concerning our less cultivated brethren as has surely never yet been collected by one writer or in one work. The first volume is occupied with Africa, that vast, and, as recent researches show, densely populated land, whose peoples present a greater variety of manners and customs and languages than any others upon the globe, and the second treats of

* "The Natural History of Man; being an Account of the Manners and Customs of the Uncivilised Races of Men." By the Rev. J. G. Wood, M.A., F.L.S., with new designs by Zwecker, Angas, Danby, Handley, &c. Engraved by the Brothers Dalziel. 2 vols 1868-70. (London: George Routledge and Sons.)

the American tribes, the inhabitants of Australia and New Zealand, with India, China, Japan, and Siam. A short notice is also given of the long-perished lake-dwellers of Switzerland.

The general plan pursued by Mr. Wood in his account of different nations is necessarily very similar. The obtainment of food and the manufacture of the means of getting it—the bow and arrow, blow-tube and poisoned shaft, the canoe, the javelin, the club, the boomerang, or lasso; war and the requisite weapons or means of defence; dress, simple and slight as it often is; and religious observances of one kind or another, constitute, with the



SURF-SWIMMING IN THE SANDWICH ISLANDS

initiatory ceremonies attendant upon entrance into manhood, marriage and death, the principal occupations and events of the life of the savage, and these, of course, form the staple of Mr. Wood's work. To do this well, however, is no slight task, considerable reading and comparison of the accounts of travellers is required, and the whole has to be worked up into the form of a continuous narrative. Mr. Wood appears to have carefully selected his authorities, and has taken only what he considers trustworthy and reliable. To give some idea of the method adopted, we may refer to his account of the Zulu Kaffirs, who he considers to have descended from the northern regions of the Continent to their present abode, and who, as is well known, are a dark-skinned but highly intelligent race. While possessing some of the characters of the negro, as the crisp, woolly hair, large wide lips, and dilated nostrils, they differ radically from him in the possession of a lofty and intellectual forehead, a more prominent nose, high cheek bones, and a nameless but decided cast of countenance. As a people, they are devoid of care, requiring no clothes, building huts of the slightest construction, and obtaining food with the greatest facility. Their reasoning powers are highly developed, and they delight in controversy. Mr. Wood then proceeds to describe the life of a Kaffir from infancy to old age, including an account of his dress, ornaments, and ceremonial observances.

To the account of the Kaffir there succeeds an equally interesting and trustworthy description of the Hottentot and of the Bosjesman or Bushman. Then follow accounts of the Korannas, the Namaquas, Bechuanas, Ovambos, and the numerous tribes of Southern and Central Africa. The facts recorded appear to have been drawn from many different sources, as Baines, Chapman, Moffat, Lichtenstein, Anderson, Burchell, Petherick, and, of course, largely from the narratives of Livingstone, Speke and Grant, Sir Samuel Baker, Du Chaillu, and Burton. The incidents selected to illustrate the character and habits of each race are, in general, very pertinent and striking, and render the whole work as amusing as it is instructive. Thus the love of finery innate in the African is well illustrated in the following story:—"An English vessel arrived at an African port, a large part of her cargo consisting of stout iron wire; nearly the whole of this was bought by the natives, and straightway vanished, no one knowing what had become of it. The mystery was soon solved.

THE LAKE-DWELLINGS OF THE ORINOCO

Suddenly the Kaffir belles appeared in new and fashionable costume. Some of them had been to towns inhabited by Europeans, and had seen certain 'cages' hung outside the drapers' shops. They inquired the use of these singular objects, and were told they were the fashionable attire of European ladies. They straightway burned to possess similar costumes, and when the vessel arrived with its cargo of wire, they bought it up, and took it home for the purpose of imitating the white ladies. Of course they had not the least idea that any other article of apparel was necessary, and so they wore none, but walked about the streets quite proud of their fashionable appearance."

The extraordinarily despotic power possessed by the chiefs of many of these tribes over the property and lives of their subjects constitutes a very remarkable chapter of their history, and is illustrated by Captain Speke's account of M'tesa, the king of the Waganda, to whom a rifle having been presented, he loaded it, and handed it to one of his pages, telling him at the same time to go and shoot somebody in the outer court. The page, a mere boy, took the rifle, went into the court, and in a moment, to Captain Speke's horror, the report of the rifle showed that the king's order had been obeyed. This barbarian was in the habit not only of flogging his wives fearfully with whips made of hippopotamus hide, but of killing them without the slightest remorse. Speke states that scarcely a day passed without some woman being led forth to execution.

In the account of the Andaman Islanders, their consummate skill in the use of the bow is described; their harpoon arrows, with which the Mincopies catch the larger fish, and which are very similar to those of Vancouver's Island, their beautiful canoes and extraordinary rowing, or rather paddling powers, beating our best crews with facility; and their family affection. To this succeeds an account of the scarcely more civilised natives of New Guinea, with their tufted hair, active climbing habits, and curious weapons. Then follows a description of the natives of the Polynesian Islands, the Fiji with their wonderful coiffures, their ingenious manufacture of veils, fans, baskets, and canoes, their warfare and cannibalism; the Solomon Islanders and natives of New Hebrides; and after these the natives of Borneo and Sumatra, and the various American tribes.

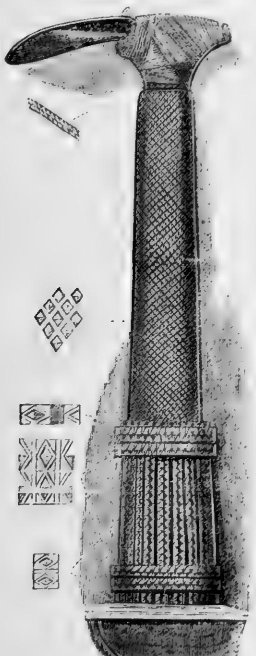
We append an account of the surf-swimming of the Sandwich Islanders, with an illustration, as copied by Mr. Wood from the now, we fear, seldom-read "Captain Cook's Voyages," who gives the following spirited account, which will not improbably be new to many of our younger readers:—"The surf, which breaks on the coast round the bay, extends to the distance of about 150 yards from the shore, within which space the surges of the sea, accumulating from the shallowness of the water, are dashed against the beach with prodigious violence. Whenever, from stormy weather, or any extraordinary swell at sea, the impetuosity of the surf is increased to its utmost height, they choose that time for this amusement, which is performed in the following manner. Twenty or thirty of the natives, taking each a long, narrow board rounded at the ends, set out together from the shore. The first wave they meet they plunge under, and suffering it to roll over them rise again beyond it, and make the best of their way by swimming out into the sea. The second wave is encountered in the same manner as the first, the great difficulty consisting in seizing the proper moment of diving under it, which, if missed, the person is caught by the surf, and driven back again with great violence, and all his dexterity is then required to prevent himself from being dashed against the rocks. As soon as they have gained by their repeated efforts the smooth water beyond the surf, they lay themselves at length on their board, and prepare for return. As the surf consists of a number of waves of which every third is remarked to be always much larger than the others, and to flow higher on the shore, the rest breaking in the intermediate space, their first object is to place themselves on the summit of the largest surge, by which they are driven along with amazing rapidity towards the shore. If by mistake they should place themselves on one of the smaller waves which break up before they reach the land, or should not be able to keep their plank in a proper direction on the top of the swell, they are left exposed to the fury of the next, and to avoid it are obliged again to dive and regain the place from which they set out. Those who succeed in their object of reaching the shore have still the greatest danger to encounter. The coast being guarded by a chain of rocks, with here and there a small opening between them, they are obliged to steer their board through one of these, or in case of failure to quit it before they reach the rocks, and, plunging under the wave, make the best of their way back again. This is reckoned very disgraceful, and is also attended with the loss of the board, which I have often seen with great terror dashed to pieces at the very moment the islander quitted it. The boldness and address with which we saw them perform their difficult and dangerous manœuvres was altogether astonishing, and is scarcely to be credited." These swimmers used often to pass nearly a mile seaward in order to enjoy the rapid motion of their return as long as possible. Both sexes and all ranks unite in it, and even the very chiefs themselves, who have attained to the corpulency which they so much admire, join in the game of surf-swimming with the meanest of their subjects. Some of the performers acquire a wonderful amount of skill, and, not content with lying on the board, sit, kneel, and even stand upon it as they are hurled shorewards by the giant waves. The boards are of various sizes, according to the age and station of the owner. For adults they are about six feet in length. They are slightly convex on both sides and are kept very smooth, all surf-swimmers cherishing a pride in the condition of their boards, and taking care to keep them well polished and continually rubbed with cocoa-nut oil.

As an example of the wonderful strength exhibited by savages, the case of the Dyaks of Borneo may be cited, one of whom, while on the march with some English soldiers, exhibited it in a very unexpected manner. "The path was a terrible one, up and down steep and slippery hills, so that the Chinese coolies, who accompanied the party, first threw away their rice, and lastly sat down and wept like children. The English sergeant, a veteran accustomed to hard marching both in China and India, broke down at the first hill, and declared his inability to move another step under the load which he carried. Mr. Brooke, who was in command of the party, asked one of the Dyaks to carry the sergeant's burden, and promised him an additional piece of tobacco. The man was delighted with the proposal, and accepted it. He was already carrying food for three weeks, his whole store of clothes, one twelve-pound shot, two twelve-pound cartridges, a double barrelled gun, a hundred rounds of ball cartridge, and his own heavy sword and spear. So little, however, was he incommoded with this, that he stuffed the whole of the sergeant's kit on his back, and walked off as easily as if the whole load were but a feather weight."

The drawing on page 11 shows the lake dwellings of the tribes inhabiting the Delta of the Orinoco, as described by Humboldt in his "Personal Narrative." "The large tract of land that forms the Delta of the Orinoco (we quote from Mr. Wood) possesses some very remarkable characteristics. It is always wet, but during several months in the year it is completely inundated, the river rising to an astonishing height, and covering with water a tract nearly half as large as England. This seems to be as unpropitious a spot as could be adopted for human habitation, and yet the Waraus (or Guarános, as Humboldt spells the word) have established themselves there, and prefer it to any other locality, probably because their strange mode of life enables them to pass an existence of freedom. Varying much in the height to which it rises, in some places exceeding fifty feet, the Orinoco has the quality of rising year after year to the same height in the same place, so that when a mark is made to designate the height to which the water rose in one year, the same mark will answer year after year with scarcely the slightest deviation." Here the Itá palm thrives, which supplies to the Warau food, drink, clothing, and residence; for, selecting four that grow near each other in the form of a square, and cutting away any intervening trees, he makes deep notches in the trunks some three feet above high-water mark. In these notches are laid beams that are tightly lashed in their places by ropes made of Itá fibres. On these leaves are laid a number of cross pieces, usually composed of the gigantic stems of the leaves, then a layer of the beams themselves, and finally a smooth coating of mud, which soon dries under the tropical sun, forming a smooth, hard, and firm flooring, that will bear a fire without risk of damage to the wooden structure below. Ten or twelve feet above the floor the Warau constructs a roof of palm-leaves, the corners of which are supported by the same trees which uphold the house.

The extreme mechanical ingenuity of some uncivilised tribes, working with very imperfect implements, is perhaps nowhere better shown than in the drawing on the opposite page of an adze made by the inhabitants of Hervey Islands, and which also gives a very good idea of the excellence of the illustrations in Mr. Wood's work, and of which the following description is given:—

"The lower part of the handle is completely hollow, the native manufacturer having contrived to cut away the wood through the intervals of the upright pillars. As these intervals are not quite the third of an inch in width the labour of removing the interior part of the handle must have been very great, and the work exceedingly tedious. Even with European tools it would have been a difficult piece of workmanship, and the difficulty is greatly enhanced by the fact that the native who carved it had nothing but a sharp stone or a shark's tooth lashed to a handle by way of a knife. The head of the adze is made of stone, and is lashed to the handle in a way exactly like that which is employed by the New Zealanders, except that it is far more elaborate. As if desirous of giving himself as much trouble as possible, the maker has employed the finest possible sinnet, not wider than packthread, and quite flat. It is laid on as regularly as if wound by machinery, and the native artist has contrived to produce the most extraordinary effects with it, throwing the various portions into a simulated perspective, and making the



THE MANGAIAN ADZE

lashing look as if there were four distinct layers one above the other."

We wish we had space to give the account of the activity of the Monkey Men of New Guinea; of the manipulative skill of the canoe-builders of Fiji, of the Zarabatana with their blow-gun, of the New Caledonian with his sling and javelin, of the extraordinary and cruel rites of the Mandans in the initiation of their youth into manhood, of the cruelty of the Tongans, and a hundred other details of interest; but our readers must refer to the work for themselves. We cannot conclude without a word of praise for the illustrations, which are extremely numerous, whilst many are original, and drawn from implements in Mr. Wood's own collection. We miss an index. H. POWER

NOTES

In stating that we believe that the English Eclipse Expedition is now finally arranged, it is due to the Government to add, and we do so with the greatest pleasure, that it is now quite clear that only a small part of the blame, which certainly attaches to some one, can be laid at their doors. In fact, explanations certainly are due from those who have had the management of the now famous Joint Committee. It appears that a deputation was named, and accepted the trust of representing the requirements of Science to the First Lord of the Treasury, which trust they neither fulfilled nor handed back to the Committee in order that another deputation might be appointed. We next hear of a letter written to the wrong Government department; and last of all, we are informed that the letters of the Government department—the last, we believe, written not later than the beginning of September—stating, among other things, that an application should be made in October, when the possibility of granting ships could be better discussed—have not yet been brought before the Joint Committee, which has just been summoned by the Secretary for the 4th of November, that is, tomorrow. It is not for us to censure such conduct as this, but it is our clear duty to point it out, and we hope the matter will be taken up. In spite of this mismanagement, however, we hear that the Government are prepared to aid both by money and ships when an application shall be made, and we cannot doubt that application will be made. There is still ample time to organise an expedition which shall do much good work, though perhaps it is too late to send out and erect the largest class of instruments. Large instruments, however, will be in the hands of the members of the American Government Expedition, so that this is the less to be regretted.

We have great pleasure in announcing that Prof. Wyville Thomson F.R.S., has been appointed by the Crown successor to Prof. Allman in the chair of Natural History in the University of Edinburgh. A vacancy is thus caused in the chair of Natural History at Queen's College, Belfast, for which we understand there are already many candidates.

The difficulty of providing funds for the establishment of a Professorship of Physical Science in the University of Cambridge has been overcome by the colleges, at a meeting of their heads, taking upon themselves a quota of the rates for improvements and other purposes in the town of Cambridge, which was formerly charged upon the University funds. This sum amounts roughly to more than twelve hundred pounds per annum; so that the University will speedily be able to avail itself of the munificent offer of the Duke of Devonshire, and will doubtless proceed at once to establish a Professorship of Physical Science, and obtain the other aids in the way of laboratory, apparatus, and assistants, that the Professor may require.

The following notices of lectures this term in Cambridge show that there is great increase of activity in teaching the various branches of Natural Science in that university. Professor Liveing gives a course of lectures on the "Experimental Laws of Heat," and also gives instruction in practical chemistry in the University Laboratory three days in the week. Professor Humphry gives a course on "Practical Anatomy," also a course on "Anatomy and Physiology," and connects with these a "Microscopical Demonstration" once a fortnight, and instruction in "Practical Histology" once a week. Professor Newton gives a course on "Zoology and Comparative Anatomy." Professor Willis gives a course on "Mechanics and Mechanism," and their application to "Manufacturing Processes" and the "Steam-engine." Professor Miller gives a course on "Elementary Crystallography and Weighing." Professor Sedgwick gives a course on "Geology." In Downing College, Dr. Bradbury lectures on "Comparative Anatomy," and Mr. Danby on "Geology." In Trinity, Mr.

Trotter lectures on "Electricity," Dr. Michael Foster on "Physiology," and Mr. Trotter on "Elementary Botany." In St. John's, Mr. Main lectures on "Chemistry," and gives practical instruction in the College Laboratory; and Mr. Bonney lectures on "Geology." Most of these College lectures are open to all the students of the University.

THE Natural Science Demyship of 75*l*. per annum for five years, at Magdalen College, Oxford, which was not awarded at the last examination, is announced for open competition in March next. Further particulars will be sent on application to the College.

THE splendid Physical Laboratory lately built at Oxford is opened this term for practical instruction in Physics, under the superintendence of Professor R. B. Clifton, F.R.S., assisted by two demonstrators.

A CHEMICAL society has been established at Zurich under the presidency of Dr. Wislicenus.

WE regret to have to announce the death, on October 26, of Dr. Thomas Anderson, Superintendent of the Calcutta Botanic Gardens. Dr. Anderson had greatly assisted in the establishment of the Cinchona plantations in British India, was the author of a large number of papers on botanical subjects, and at the time of his death (on sick leave in this country) was engaged, in conjunction with Dr. Hooker and Dr. Thomson, on the new Flora of India.

THE death is announced of the Rev. F. Bancks Falkner, late head-master of Appleby Grammar School, a gentleman well known from his numerous and elaborate meteorological reports and letters, which mostly appeared in the pages of the *Standard* and *Scientific Opinion*.

AT the first of the winter *soirées* to be held on Monday evening, November 14, at 8 o'clock, at 27, Harley Street, Mr. A. R. Wallace will read "An Answer to Dr. Hume, Lecky, and others, against Miracles." A discussion will be invited.

THE following officers are proposed for election by the Council of the London Mathematical Society at the general meeting to be held on Tuesday evening next:—President, W. Spottiswoode; Vice-presidents, Prof. Cayley, Prof. Henrici, Prof. H. J. S. Smith; Treasurer, Prof. Hirst; Secretaries, H. Jenkins, R. Tucker.

THE fourth opening *conversazione* of the Hackney Scientific Association took place on the 25th October, at the Meeting Rooms, New Tabernacle, Old Street Road, E.C. The objects exhibited were lent entirely by the members and some friends, and comprised an unusually fine display of microscopes of the most powerful description. Geology was well represented by a very rare collection of fossil mammalian teeth from the Freshwater Post-tertiary beds in the Lea Valley, exhibited by Mr. R. E. Olliver, also a fine series of Coal-measure fossils by Mr. W. Appleford. Astronomy was unusually well represented by numerous objects, amongst which were two refractor telescopes, exhibiting convenient forms of mounting, also numerous sketches by Mr. W. R. Birt, exhibiting the most recent progress in selenography. We must not omit to notice a numerous collection of astronomical drawings, by Mr. A. P. Holden, amongst which were four very fine sketches of the recent great sun-spot.

A NATURAL HISTORY SOCIETY was established a year ago in King Edward VI. Grammar School, Birmingham, and is now in active operation. A school collection has been commenced, with a view to a future museum.

THE Special Commissioners appointed for the purposes of the Public Schools Act, 1868, in virtue of the powers conferred upon them by that Act, have made five statutes for determining and establishing the constitution of the New Governing Bodies of the Schools of Winchester, Harrow, Rugby, Shrewsbury, and Charterhouse. These statutes have been laid before Her Majesty in Council, and are published in the *London Gazette* of Tuesday, Oct. 25. Notice is given that it is lawful for the bodies or persons authorised so to do in that Act, within two months from the date of the publication of this notification, to petition Her Majesty in Council to withhold her approval from the whole or any part of such statutes.

AS the subject of hereditary deformities is attracting some attention in our columns, it may be worth while to call attention to Brown-Séquard's experiments on epileptic guinea-pigs detailed at the recent meeting of the British Association. Dr. Brown-Séquard produced epileptic fits in the guinea-pigs either by the section of one-half of the spinal cord, or by the division of the sciatic nerve on one or both sides. During the fits it sometimes happens that the hind foot gets between the teeth, and is bitten. The animal, on recovery from the fit, tastes the blood, and if it be one in which the sciatic nerve has been divided, proceeds to nibbl off the two outer toes, which have entirely lost their sensibility from the operation on the nerve. In breeding from pairs of this kind, the offspring is without the two toes of which the parents have deprived themselves; and in these cases all the offspring become, as they grow up, perfectly epileptic; while in ordinary cases epilepsy is only rarely transmitted hereditarily. Other peculiarities existing in these epileptic guinea-pigs were also found to be transmitted to their offspring; and in dissection of the hereditarily malformed animals, a node was found on the sciatic nerve corresponding to that formed after section of the nerve in the parent.

IT may interest some readers to know that the Board of Trinity College, Dublin, have expended about 2,000*l*. in draining the College park. Situate as the park is, in the very centre of the city, its drainage will confer a considerable benefit on the city. Dublin will also be much improved by the space of ground which the College authorities are giving to the city in College Green, as well as ornamented by the new cut stone wall and handsome iron railings which take the place of the old irregular quadrangle in front of the College. The College share of the expenses amounts to 2,000*l*.

WE have received the half-yearly Report of the Marlborough College Natural History Society, from which it appears that the Society has entered on the seventh year of its existence. During these years it has undoubtedly greatly strengthened the love of Natural Science among the *alumni* of the College, an evidence of which is the publication during the last half-year of "The Birds of Marlborough" by an old member of the Society, E. F. im Thurm, a little volume for which we would wish a greatly increased circulation. The officers regret that the number of members of the Society is not yet commensurate with the number in the College who take an interest in Natural History. In no more practical way can the love of a study of nature be fostered than by the encouragement of societies similar to this.

IT is stated that the Botanical Gardens at Strasburg were used during the siege as a burying-ground.

THE twentieth part of the late Prof. Schnizlein's "Iconographia familiarum naturalium regni vegetabilis," is published under the superintendence of Dr. Eichler, of Munich. This magnificent work, commenced seven and twenty years since, is now completed in twenty parts.

AS Colombia in the last year exported about 3,500,000lbs. of cinchona bark, valued at 87,000*l*., the Government there naturally looks with some interest on the trade, and is desirous to improve it. It is curious to see in the official report of the Secretary of the Treasury a detailed account of the successful measures of our Government for the cultivation of cinchona in India.

AN earthquake was felt generally in the Natal colony and the Orange River Free State, about 3.45 P.M. on the 3rd August. It did no material damage. It was recorded at Bloem Fontein, in the Free State, and at Pietermaritzburg, Durban, New Guelderland, Ladismith, Noodsberg. The course appears to have been from N.W. to S.E.

THE three most recent parts of the *Bulletin* of the Imperial Academy of Sciences of St. Petersburg contain the following articles :—Quelques propriétés du fer déposé par la voie galvanique, R. Lenz ; Rapport sur un voyage entrepris dans l'intérêt de la linguistique, F. J. Wiedemann ; Remarques sur les Echinoderes, El. Metschnikoff ; Sur le poil du *Rhinoceros tichorinus*, J. F. Brandt ; Sur less congruences binômes exponentielles à base 3 et sur plusieurs nouveaux théorèmes relatifs aux résidus et aux racines primitives, V. Bouniakowsky ; Note relative à une demonstration, donnée par Cauchy, des équations générales de l'équilibre, J. Somoff ; Sur les sentences de Publilius Syrus, A. Nauck ; La Métrique pâlie Vuttodaya, J. Minayeff ; Sur l'histoire composée en arménien par Thoma Ardzrouni, X^{e} s., M. Brosset ; Sur un théorème relatif à la théorie des résidus et de son application à la démonstration de la loi de reciprocité de deux nombres premiers, V. Bouniakowsky ; Remarques et rectifications concernant l'histoire naturelle des Alcides, J. F. Brandt ; Sur le symbole de Legendre $\left(\frac{a}{p}\right)$, V. Bouniakowsky ; Embryologie du *Phthirius pubis.* (avec une Planche.), Os. Grimm ; De l'influence de la chaleur sur l'élasticité du caoutchouk, J. Schmulewitsch ; Notice sur Ak-tau et Kara-tau, montagnes dans la presqu'île de Mangyschlak, côte orientale de la mer Caspienne, G. V. Helmersen ; Sur les dérivés de la série isocaprine, A. Borodin ; Détermination du coefficient constant de la précession au moyen d'étoiles de faible éclat, M. M. Nyrén.

A RIVAL to the far-famed Mont Cenis tunnel is announced from America. The tunnel through the Hoosac Mountain, on the Troy and Greenfield Railway, is steadily progressing, and has now overcome the great difficulties with which it started. It is $4\frac{3}{5}$ miles in length (more than half that of Mont Cenis), and of this distance about one-third is already penetrated. The work is actively proceeding night and day from both ends, and it is expected it will be finished before the expiration of the contract in 1874.

FURTHER favourable reports of ipecacuanha cultivation in India have been received. The Conservator of Forests states that the plants in the gardens at Nelamboor are doing well, and that some of the fleshy leaves were four inches long.

A UNIVERSITY FOR TEXAS

THE Rev. W. H. Sent has been for some time past in Europe, with letters from the late President of the United States, the Governor of Texas, and other distinguished Americans, as the agent of the Soule University and the Chappell Hill Female College, two literary institutions located at Chappell Hill, Washington county, in the State of Texas. His aim is so to enlarge and furnish them, especially the University, which has a medical department in Galveston, as to develop a great and permanent centre of learning and science. Considering the vastness and the resources of Texas, its position as bordering on semi-civilised regions beyond, the rapid increase of its population, which includes a large European element, and its growing commercial relations with Europe, especially with this country, such an enterprise as this must commend itself as one of great importance, and of general interest.

The degree of success that has attended the agency is, indeed, extraordinary. Mr. Sent received contributions of books, specimens, &c., from various departments of the United States Government, from Prof. Agassiz, Yale College, the Smithsonian Institution, and other eminent sources in America ; and in Europe from the Emperor, the French Government, the Jardin des Plantes, the great French authors, &c., and the same line of success was continued in Belgium, Holland, Denmark, the various German States, and elsewhere. We are glad to know that he is meeting with encouragement in London from the Admiralty, the Geological Survey, the University of London, from many of our publishing houses and other sources. The agent is applying to many of our Learned and Scientific Societies for their transactions, which will, we doubt not, be cheerfully contributed. The agency involves a patient, persevering effort to accomplish a very important work. We most heartily commend the enterprise to the friends of education in this country.

Any contributions of books, or of botanical, geological, or mineralogical specimens may be sent (with a statement of the sources whence they come) to care of Messrs. Trübner and Co., 60, Paternoster Row, London, or to Messrs. Caleb Grimshaw and Co., Liverpool.

EARTH CURRENTS

IT has been my pleasure at different times to call attention to the connection that exists between the Auroræ Boreales and that great apparent rush of electricity through the crust of the earth which eagerly seizes upon the easy paths, offered to its passage by the wires of the telegraph, and by filling them with electricity, produces what are called "earth currents," or "deflections." The aurora is always accompanied by such displays, but it is rarely in England that they are of such strength as absolutely to break down telegraph communication. The earth currents of Oct. 24 and 25 have only been equalled by those which occurred in 1859.

The following extracts from the diary of one of the large telegraph stations in the South of England will be found interesting :—

Oct. 24,	5.0 P.M.	Slight deflections on all long circuits.
„	5.30 „	Gradually increasing.
„	6.0 „	Very strong ; circuits suspended for ten minutes.
„	7.0 „	Gradually decreasing.
„	8.15 „	All circuits right.
Oct. 25,	3.0 „	Deflections, which have been intermittent all day, or very strong.
„	3.30 „	Circuits nearly all stopped.
„	4.0 „	Working through on some circuits, but slow.
„	5.0 „	Deflections decreasing.
„	5.45 „	On again; all circuits suspended.
„	6.15 „	Deflections decreasing again.
„	7.0 „	Circuits clear.

This is only a sample of what occurred simultaneously all over England, and probably the globe. The currents were very irregular in their direction and very variable in their strength. Circuits running S.W. to N.E. are usually most powerfully affected, but on this occasion all directions seemed equally affected.

Where two or more wires run between two stations, the effect of these currents upon the working is easily remedied by substituting the second wire for the earth to complete the circuit. This practice was largely adopted on Monday and Tuesday last.

The most striking fact observed was that on each occasion the currents *ceased* when the auroral display *commenced.* I have not noticed this before, probably because the cessation of the one phenomenon and the first appearance of the other have scarcely ever before been so strongly indicated.

W. H. PREECE

DR. C. W. GÜMBEL ON DEEP-SEA MUD

DR. C. W. GUMBEL has recently published an important paper, containing an account of some highly interesting investigations on Deep-sea Mud. Sir R. Murchison and Professor Huxley provided him with a large quantity of mud, taken up from the Atlantic at lat. 29° 36' 54" N., and long. 18° 19' 48" W., at a depth of about 2,350 fathoms. This he first cleared, by long-continued washing, from all sea-salts soluble in water; then he divided it, by filtering, into three parts. In the first Foraminifera and larger organisms predominated; the second consisted of a sediment easily distinguished from the first, fine but heavy; the third was fine and flaky, remaining lightly suspended in water, and consisting almost exclusively of *Bathybius*, Coccoliths, Coccospheres, together with other organisms of the smallest kind (Diatoms, Radiolaria, Sponge-spicules, and a very few of the smallest Foraminifera). "Dried to about 100° C." says Dr. Gümbel, "10 per cent. of the mud consisted of large Foraminifera; 1·3 per cent. of fine, heavy mud; and 88·7 per cent. of finest *Bathybius* mud. The 10 per cent. part consisted mostly of *Globigerina*, which occurred in an astonishing variety of forms, from the smallest shapes to figures of a considerable size, and could easily be distinguished as *Gl. bulloides* and *Gl. inflata*. Next to these in number were *Orbulina universa, Cristellaria crepidula, Truncatulina lobatula, Discorbina rosacea, Rotalia soldanii, R. orbicularis, Pulvinulina elegans; P. micheliana, Nonionina umbilicata, Polystomella crispa, Lituola globigeriniiformis*, with many other (but more dismembered) species. Along with these there were individual specimens of large *Radiolaria*, Siliceous Sponge-spicules, Diatoms, shells of *Ostracoda*, torn pieces of sponge and (very rarely) of *Echinodermata*, and fragments of wood, which were very decidedly distinguishable. It is a question whether the latter was a part of the apparatus used in raising the mud. It is in the highest degree remarkable that all traces of Bryozoa, corals, and firm pieces of more highly-organised animals, were wanting, or at least were very rare.

"The fine heavier mud which composes the sediment contains, for the most part, inorganic elements, with fragments which consist essentially of carbonate of lime, and which, on being dissolved in acids, leave behind cuticular membranes and flakes, which partly gave the reaction of conchiolin. It appears to follow from this, that these pieces of calcareous matter, although I could discover by the microscope no structure in them, are essentially derived from pounded molluscous shells. The remaining portion, which was insoluble in diluted acids, was composed of irregular, for the most part lump-shaped, granules of quartz, of clearly recognisable scales of mica, of dust, and of magnetic iron, which could be drawn out by the magnetic needle; of single red, blue, and dark green transparent pieces of mineral; and of grains of crystal, of a peculiarly dark irridescent brilliance, which I can refer only to Labradorite. The polarisation and stauroscope apparatus was used for the purpose of determining these inorganic ingredients.

"These inorganic elements of the Deep-sea Mud, found at such a distance from land, appeared to me worthy of the greatest consideration. Their origin can scarcely be ascribed to the loosening of the perhaps rocky bottom of the sea, at the point where it was sounded. They rather prove that inorganic substances, which are derived from the rocky masses of the land by mechanical destruction, are conveyed by ocean currents to parts of the sea the farthest removed from land. This would render easily explicable the admixture of inorganic elements in many ocean sediments of ancient times. The explanation of clayey or marly interpositions would be made much less difficult. If heavy masses of mineral are transported so far, how much more easy, would be the transportation of clayey mud which remains so lightly suspended in the water! It is almost self-evident how quantities of clay or marl may be brought to a stand at certain parts of the high sea, marked out beforehand by the direction of the ocean currents and the configuration of the bottom of the sea, and when the direction of the currents changes, may come to form even alternate strata of chalk and marl. We thus obtain a mode of explaining the formation of many marl deposits, which is at once natural and simple.

"The third portion of the Deep-sea Mud is worthy in a high degree of the interest both of the zoologist and the geologist, whilst it gives scope for many far-reaching theories. If we first analyse it microscopically, the substance, which resembles a white clay mud, resolves itself, apart from the intermingled minutest *Globigerinæ* and some few other Foraminifera, into a heap of little granules, the so-called Coccoliths (Discoliths and Cyatholiths), and of granulous flaky little lumps, the so-called *Bathybius*, compared with which all other ingredients,—the siliceous-shelled Diatoms, and *Radiolaria*, and also perhaps the so-called Coccospheres and other small organic bodies excepted,—are of very secondary importance.

"The part of the Deep-sea Mud which is made up of Diatoms and *Radiolaria*, together with Sponge spicules, is of especial importance, because it consists to no inconsiderable extent of silica, and appears to be the source from which the siliceous concretions in many chalk formations have drawn their materials. That these form no inconsiderable part of the composition of Deep-sea Mud may be clearly seen by removing the chalk by means of acids, and the organic matter by heat or by sulphuric acid. There then become visible the most beautiful forms of Diatoms, with especial frequency, *Gallionellæ, Coscinodisci*, and *Naviculæ*, more rarely *Actinocyoli, Pleurosigma, Rhabdonema, Grammatophora*, and others, of which many, concealed in the network of granulous *Bathybius* masses, were formerly scarcely visible. Many forms of extremely beautiful *Radiolaria* were also seen, together with simple Sponge-spicules. Lastly, we remark some slight fragments of plants, which may belong to the species of *Saprolegnia* and *Protoccus*."

Speaking of the Coccoliths and the *Bathybius*, Dr. Gümbel says he is in a position to confirm the conclusions of Profs. Huxley, Carpenter, and Haeckel with respect to their organic nature. In a note he adds, "I have already stated my opinion on this subject (NATURE, April 1870) but must here rectify a mistake in that communication, namely, that the organic matter of the Coccoliths yields with iodine, blue, therefore cellulose, reaction. This colouring, I am now convinced, is not the consequence of chemical action, but a phenomenon of refracted light, such as occurs with small thin leaves or membranes when greatly magnified."

After detailing some observations, microscopic and chemical, on *Bathybius* and Coccoliths, Dr. Gümbel proceeds to speak of the further distribution of the latter. "First," he says, "on looking through the Algæ, Hydrozoa, Polyps, Corals, &c., which occur on shallow sea-coasts, such as may easily be met with in every botanical and zoological collection, I succeeded in numerous instances in finding Coccoliths in the places where they had grown, and not seldom, *Bathybius* at the same time. These investigations were extended to points on the coasts of almost all seas, and now, instead of the statement lately made that the organisms in question thrive only at a depth of 5,000 feet, I am in a position to assert on a proved fact, that Coccoliths (*Bathybius*) occur *in all seas and at all depths*. This deprives these minute bodies of a certain air of wonder with which they were surrounded, as the offspring of the profoundest and most secret depths of the ocean; but by their astonishingly wide distribution and their vast numbers, which stamp them as one of the most essential members of rock-forming substances, they gain infinitely in scientific interest."

Dr. Gümbel maintains that the distribution of Coccoliths in time is not less remarkable than the present distribution in space. There is proof, he says, that they are to be found in "almost all sedimentary formations." Referring to their distribution in various formations, he says:—"But besides the Coccoliths another ingredient demands attention. In the case of the chalk of Meudon, rich in Coccoliths, if the carbonate of lime be removed by means of diluted acids, there remains a flaky and cuticular residue, in which are found thin, transparent flakes, full of the smallest granules, and resembling *Bathybius* in a high degree. . . . . This places their organic nature beyond question, and firmly establishes their relationship with the *Bathybius*. The imperishableness of this substance is indeed very remarkable." After stating that the Coccoliths occur in all the soft marls and limestones of the Jurassic and Liassic formations—"The Muschelkalk," continues Dr. Gümbel, "appeared for a long time to be proof against every experiment. Every specimen of marl which I examined was apparently free from Coccoliths. At last I had the good fortune to discover traces of them in a somewhat impure piece of rock-salt from Wilhelmsglück. Even here they show themselves extremely sparingly, but in the company of flakes, which are not unlike *Bathybius*. To the present time I have in vain examined the similar rock-salts of Berchtesgaden and Stassfurt; and as yet indications of Coccoliths in the Permian formation and the Coal-measures are wanting. On the other hand, the soft marls of the mountain limestone of Regnitzlosau, the soft marls of the Conodont strata of the Baltic provinces, the Trenton marl of New York, and even the siliceous limestone of the Potsdam sandstone, contain some traces, although to an extremely small extent.

"These facts all point to the conclusion that in the majority of calcareous marine deposits, the Coccoliths originally formed a more or less essential part of the calcareous masses, and that in thick or granulous, and particularly ancient limestone rocks, they can no longer be perceived, either on account of the opaque character of the rocks, or because they have been made by some change wholly or in part unrecognisable, or have been altogether destroyed. I have been able by some experiments to throw further light upon this subject. That these smallest organic bodies can be recognised in hard limestones only in the rarest cases, even when it contains them in great numbers, I convinced myself by means of thin slices, which I made from Deep-sea Mud, thoroughly dried and rendered hard by repeated soaking in diluted Canada balsam and by heating, and also from writing chalk, made hard in the same way, and rich in Coccoliths The infinite numbers of finest granules and rings are so massed together, one over the other, that it must be regarded as an extremely rare case when a Coccolith is clearly seen here and there at the very thinnest edges."

THE BRITISH ASSOCIATION

SECTIONAL PROCEEDINGS

SECTION A.—MATHEMATICAL AND PHYSICAL SCIENCE

On a new Electro-Magnetic Anemometer and the Mode of Using it in Registering the Velocity and Pressure of the Wind.—Mr. J. J. Hall. The anemometer consists of two parts, viz.—velocity apparatus and registering apparatus. The first consists of a set of Robinson's hemispherical cups, which communicate their motion downwards into a brass box, where it is reduced in angular velocity, and causes a contact disc or *commutator* (in which two platinum contact pins are fixed equidistant from one another) to revolve in $\frac{1}{10}$th mile. An insulated metallic lever, having a platinum working face, stands on either side of the disc, so that upon the completion of every $\frac{1}{500}$th mile one or other of the contact pins comes in contact with the two levers, thus uniting them and completing the circuit. The levers are raised a few degrees and then fall back to their normal position ready to be taken up by the next pin, and so on. The recording apparatus consists of a train of wheels and pinions working in a frame or between two brass plates, the arbors of which project through a dial-plate whereon the circles and figures are engraved and carry the hands. These wheels are driven by a weight attached to a line wound round a barrel, and a locking-pin disc (the pinion of which works in the first wheel) is released at every contact of the cup-apparatus by an electro-magnet which unlocks the pin-disc and allows the first hand to advance $\frac{1}{500}$th mile on the graduated dial by a jump similar to the minute hands in remontoire clocks. By turning on a "strike-silent" stop a hammer lever is brought into connection with the escapement and strikes a bell at every contact. By this arrangement the observer has nothing to do but to notice the seconds-hand of his watch or chronometer while he counts the number of times that the bell is struck, each of which corresponds to the five-hundredth part of a mile, and by a formula arranged (and exhibited) by Mr. Hall (who has also arranged a comprehensive series of tables for use with this instrument) the hourly velocity may be readily deduced. In noting velocities extending over long periods of time, the instrument is read in the same manner as the ordinary cup and dial anemometer, or as a gas meter. By means of the formula before mentioned (although the unit of measurement in this instrument is five-hundredths) the observer may arrive at results as near the truth as if the instrument were capable of registering the one-thousandth part of a mile, while the great advantage lies in the fact that the battery power is less called into action, from which we may infer its elemental duration will be considerably longer.

A Magnetic Paradox.—Mr. S. Alfred Varley, Assoc. Inst. C. E. The author stated he had termed the instrument a Magnetic Paradox because the phenomenon exhibited by it was the apparent repulsion of soft iron by a magnet. The apparatus consisted of a compound magnet in a box, and when pieces of soft iron were placed on the box over the poles they became magnetic by induction and were attracted by the magnet; but if a soft iron bar not by itself magnetic was approached near to the pieces of iron, they leapt away from the magnet in the box and became strongly attached to the soft iron bar, the pieces of iron appearing to be repelled by the magnet and attracted by the iron bar. The author stated the explanation demonstrated the duality of the magnetic force, and it would also prove, did we not already know it, that magnetic force was transmitted only by induction. He stated that if a piece of soft iron were placed over the poles of a magnet, the magnet developes the magnetic forces resident in the iron by separating them, and the iron is attracted only by virtue of the forces existing in the iron itself, and to the extent to which the forces are separated. If the magnet be bent, bringing the lower pole round and over the piece of soft iron, the magnetic forces resident in the soft iron will be more developed; but if the piece of soft iron be midway, it will not be attracted, as the forces on either side are equal and balance; another attraction will, however, be manifested if one pole be nearer to the piece of iron than the other. If, instead of bending the magnet as just described, the piece of soft iron placed over the magnet be approached by a soft iron bar, the magnetic forces separated and rendered active in the piece of iron will develop the magnetic forces resident in the iron bar, and if the bar opposed no resistance to the assumption of the magnetic condition, it would exert an attractive force for the piece of soft iron equal to that exerted by the magnet, provided always that the bar was at the same distance. It was stated that as the mass of iron in the iron bar was much greater than that of the piece of soft iron, the resistance opposed by the bar to polarisation was comparatively small, and might be disregarded, and consequently it followed that as the dual forces resident in iron are equal, and the one force cannot be developed without equally developing the other; when the iron bar was approached nearer to the piece of soft iron it became attracted, leaping away from the magnet and attaching itself to the iron bar, and this notwithstanding that the attractive force exhibited by the iron bar has been called into being by the magnet in the box, which is nearer to the piece of soft iron than it is to the iron bar. The iron bar also collected the magnetic rays of force issuing from the magnets, and consequently it exerted a greater attraction for the piece of soft iron than any individual magnet forming part of the compound magnet. This was shown by placing a piece of soft iron on the pole of one of the magnets and removing it from the pole by the superior attractive force of the iron bar. It was also shown that if only the thickness of a piece of writing-paper were placed between the magnets and the piece of soft iron, the appearance of repulsion could be prevented.

SECTION B.—CHEMICAL SCIENCE

On the Separation from Iron Furnace Cinder of Phosphoric Acid for Manurial Purposes.—Mr. James Hargreaves. While the author was engaged in an attempt to produce a good serviceable steel direct from phosphoric pig-iron, by the use of nitrate of soda, the fact forced itself upon his attention that phosphorus had previously been too much looked upon as something to be *got rid of*, and not sufficiently as something to be *got hold of*; and that to effect the latter would be the best means of effecting the former. When phosphoric pig-iron is converted into malleable iron, the phosphorus is, in great part, transferred to the refinery and puddling furnace cinder in the form of phosphate of iron, the amount varying with the composition of the pig-iron which yields it. The refining and puddling furnace cinder from Cleveland pig-iron generally contains from 3 to 7 per cent. of phosphoric acid, which is from one-fourth to one-half the amount contained in good commercial soluble phosphate of lime. This cinder is sometimes again used for the manufacture of pig-iron, but the product is of small commercial value on account of the accumulation of phosphorus in it. The concentration of the phosphorus from the pig-iron into the cinder in the form of phosphate of iron renders it more easy and practicable to separate, when the preparation of compounds of phosphoric acid is the object in view, as there is a smaller bulk of material to be treated to obtain a given amount of this product. The phosphoric acid may be separated either in the form of soluble superphosphates of lime and magnesia, or of the alkaline tribasic phosphates.

On the Retention of Organic Nitrogen by Charcoal.—Mr. Edward C. C. Stanford, F.C.S. In this paper the author submitted some incomplete researches, as a first instalment of what promises to be a wide field of inquiry, viz., the action of charcoal on organic nitrogenous matter. He was desirous of knowing whether or not a loss of nitrogen occurs when that form of matter remains in contact with charcoal, and if so, what becomes of it. If any loss occurs, it would invalidate the process recommended by the author at the Exeter meeting of the Association, viz., that of using charcoal as a means of securing the whole value of town excreta. He said that he had shown last year that, with either fluid or solid excreta, there was no loss, as far as his experiments had then extended; and he had pointed out, also, that he expected no loss from oxidation, as both must already be regarded as oxidised compounds. His experiments since had extended over a long period, and he had included meat as one of the nitrogenous matters used; in all, however, he had found no loss of nitrogen, no oxidation, and no formation of nitrates.

SECTION C.—GEOLOGY

On a Census of the Marine Invertebrated Fauna of the Lias.—Mr. R. Tate. The author gave an analysis of the fossils, but desiderated more precise data before exact results could be obtained.

On the Formation of Boulder Clays and Alternations of Level of Land and Water.—Rev. J. Gunn. The author illustrated his own opinions, which were completely at variance with the generally accepted interpretation of the origin of these beds.

On Some Cases of the Recent Conversion of Glacial Drifts into what Appears to be Middle Drift.—Mr. G. J. Stoney.

On the Occurrence of Pebbles and Boulders of Granite in Schistose Rocks in Islay, Scotland.—Mr. J. Thomson. The author described the different rocks exhibited in a section across Islay from west to east, and the position of the metamorphic rock in which the boulders occurred which underlies a bed of quartzite seventy feet thick. Specimens of some of the smaller boulders with their interesting matrix still attached to them were exhibited. The bed probably indicated one of those recurring glacial epochs which had formed the subject of Mr. Wallace's communication to the section.

Diamonds of South Africa.—Professor Tennant.

Changes of Climate.—Mr. R. A. Peacock. These were due, according to the author, to rain and rivers, to denudations, to risings and sinkings of land, and to the great range of temperature in interplanetary space and on the various parts of the earth's surface. The warm, genial climate of the Carboniferous period he ascribed to the absence of high hills at that time on the globe.

Sur le terrain Silurien du centre de la Belgique.—Professor Malaise. The author described the series of beds with their fossil remains, and considered that they represented a portion of the Middle Silurians, more extensively developed in Belgium than in Britain.

On the Remains of an Insect discovered in the Carboniferous beds at Huyton.—Mr. Clementshaw exhibited the specimen of the insect, and pointed out the characters upon which he ventured to refer it to the *Fulgoridæ.*

Notes on a Merionethshire Gold Quartz Crystal, and some Gold found recently in the River Mawddach.—Mr. T. A. Readwin.

SECTION D.—BIOLOGY

Department of Anatomy and Physiology

On the Connection of the Hyoid Arch with the Cranium.—Prof. W. H. Flower, F.R.S. In the sheep, as is well known, the anterior arch or cornu of the hyoidean apparatus is described as consisting of three bones, of which the uppermost is by far the largest and most important, and has received the name of stylo-hyal. This bone is long, compressed, and at the proximal end enlarges and divides into two short branches, by the anterior of which it is continued as a cartilaginous band to the cranium. The upper end of this band is again ossified in the form of a curved cylindrical plug of bone, with a truncated lower extremity, lying in a groove on the side of the tympanic bone, the edges of which groove meet around it in adult animals, and often become ankylosed with it; but this is only a secondary connection. The primary connection is with the periotic or petro-mastoid bone, immediately in front and to the inner side of the stylo-mastoid foramen. In embryonic specimens it can be traced as a distinct band of cartilage lying to the anterior and inner side of the lower end of the Fallopian aqueduct, and passing to the upper and back part of the tympanic cavity, near to the spot from which the stapedius muscle takes origin. This is then the true proximal extremity of the anterior arch of the hyoidian apparatus, if we leave out of consideration the stapedius and incus which there is reason to believe are developed from the same rod of cartilage—a question which is not discussed in the present communication. Whatever may be the case with regard to the origin of the last-named parts, it is a subject of easy demonstration that in the sheep there is an ossified portion of the upper end of the hyoid arch, above and distinct from the stylo-hyal, which becomes firmly united with the periotic, and which may ossify either from a separate centre or by extension of bone from the periotic. Whether it should be considered as a process of the periotic or as a separate element may still be a matter of opinion; but the existence of such a part as a distinct portion of the hyoid arch requires recognition. It may be conveniently distinguished by the name of *tympano-hyal*, as it is always in relation with the tympanic bone, and continues the hyoid arch up to the wall of the cavity of the tympanum.

This portion of the skull can be distinctly recognised at the spot in dicated (*i.e.* to the anterior and inner side of the stylo-mastoid foramen) in almost all mammals, though in very different degrees of development, usually in accordance with the size and amount of ossification of the remainder of the anterior arch. Thus, in those of the Ungulata, as the ruminants, and especially the horse and rhinoceros, in which the stylo-hyal is very largely developed, the tympano-hyal is most conspicuous, but where, as in the pig, the anterior arch is little ossified, the tympano-hyal is comparatively rudimentary. In the cetacea it is quite distinct, though small, and a fine band of cartilage can often be traced from the upper end of the stylo-hyal into it, embedded in the great ligamentous mass which attaches that bone to the exoccipital and surrounding parts of the cranium, and which of course is only a secondary connection.

In man, this bone or process is also quite distinct, although it seems to have been generally confounded with the stylo-hyal. The so-called styloid process of the temporal bone has long been known to have a separate centre of ossification, and is also generally recognised as the homologue of the stylo-hyal of other mammals, one of the main points of difference being, that whereas in all others it is an independent bone not connected directly with the cranium, in man it is always ankylosed to the "temporal," or forms a process of the skull.

If a human skull at the period of birth is examined, a very small round piece of bone surrounded by a deep groove can be seen exactly where the tympano-hyal is found in the sheep, just behind the posterior limb of the inverted arch formed by the tympanic bone, and in front and to the inner side of the stylo-mastoid foramen. This increases somewhat in size as age advances, forming a distinct process, supported, and partly embraced in front by the vaginal process of the tympanic. The true styloid or stylo-hyal at birth is a slender rod of cartilage, often partially ossified in the centre, and invested by a strong fibrous sheath, from which the stylo-hyoid, stylo-glossus, and stylo-pharyngeus muscles take origin. Though it occasionally becomes ankylosed in the adult with the tympano-hyal, as is the case with those skulls which have very long styloid processes, this does not occur so frequently as is described in most works on anatomy. In the large majority of skulls, before middle age, the stylo-hyal is free, and is commonly lost in maceration. The short process which is always present, and which is commonly considered as a rudimentary styloid process, is really a distinct portion of the hyoid arch, corresponding with the tympano-hyal of the sheep.

The communication was illustrated by specimens and diagrams.

On the Correspondence between the Anterior and Posterior Extremity, and the Modifications of the Position of the Limbs in the higher Vertebrata.—Professor W. H. Flower, F.R.S. This communication was chiefly devoted to an exposition, by means of specimens and diagrams, of the views held by most English anatomists of the serial homologies of the different bones of the extremities, founded upon comparison of the anterior, cephalic, or preaxial border of the one, in the primitive position, with the same border of the other, which leads to results opposed to the views of Wyman and other American anatomists, founded upon the principle of antero-posterior symmetry.

On Lefthandedness.—Dr. Pye-Smith. The author referred to the prevalence of this condition as an occasional variety as far back as tradition goes, and in various parts of the world. Like righthandedness, it should be regarded as a functional specialisation, not a structural transposition. That it does not depend on transposition of the viscera is proved by several cases; and also that it does not result from the abnormal origin of the subclavian artery, as referred to in a previous number of NATURE. Righthandedness is probably the immediate result of some structural difference between the two cerebral hemispheres. Gratiolet's statement, that the left hemisphere is earlier developed, is contradicted by Ecker, Vogt, and Callender; but Broca's, that it is normally heavier than the right, is confirmed by Dr. Boyd. The author then spoke of the possible truth of Brown-Séquard's theory of the left hemisphere presiding specially over animal, the right over organic functions. Normal aphasia with right hemiplegia was contrasted with cases cited from Dr. Ogle and Dr. Hughlings Jackson, of left-handed persons with left hemiplegia and aphasia. The primitive condition was probably one of perfect bilateral structural symmetry and ambidextrous function. The normal condition at present is the result of hereditarily transmitted specialisation of structure and functions, both the result of some advantage resulting to individuals using the right hand, eye, or foot, for the performance of more specialised functions than those of swimming, climbing, &c., such for instance as carrying weapons or nursing children. Lefthandedness would then be explained as a more or less complete reversion to an ancestral condition. Right and Lefthandedness should, therefore, be compared with such deviation in function and structure as is observed for instance in the clelæ of the higher Crustacea, while transposition of viscera is to be classed with the reversed twist occasionally seen in the skull of *Pleuronectidæ* and the shells and entire bodies of Gasteropoda.

Professors Burdon Sanderson and S. Stricker read a paper on *A New Method of Studying the Capillary Circulation in Mammalia.* The circulation was studied in the omentum of a guinea-pig immersed in a solution of salt and water of a certain strength and temperature, the animal being thoroughly chloralised.

Contributions to the Migration Theory.—Richard Caton, M.D. This paper contained an account of a number of experiments on the capillary circulation of the frog, fish, and tadpole in reference to the interesting phenomenon of the migration of blood-corpuscles out of the vessels. The opinion was expressed that this occurrence was chiefly due to congestion, and also that there were grounds for considerable doubt as to whether it had any connection with the suppurative process, as hitherto supposed to be the case. This paper was read immediately after those of Dr. Burdon Sanderson and Prof. Stricker, and the three were discussed together.

On the Antiseptic Treatment of Contagia as Illustrative of the Germ Theory of Disease.—Mr. Hope. The author gave some valuable details as to his treatment of the rinderpest which broke out upon his experimental farm in Essex in 1867. The majority of between 260 and 270 cows were attacked by that disease. He injected carbolic acid through either the mouth or rectum, and 111 of those cows so treated recovered. The remainder not so dealt with died or had to be slaughtered. He also argued that the chemical instead of the medicinal treatment of contagion was much better both in respect to men and the lower animals. He also gave illustrative cases of scarlet fever, with the view of showing that the sipping of a very weak solution of carbolic acid, sprinkling body, clothes, carpets, &c., was highly beneficial in its effects.—Dr. Baylis, medical officer of health, Birkenhead, agreed with the reader in his views regarding rinderpest, but not entirely with his treatment of fever. He (Dr. Baylis), speaking of the unsatisfactory manner in which that subject was treated by the British Association, expressed a hope that before next year's meeting they would institute some experiments as to the action of disinfectants.

Department of Ethnology and Anthropology

Dr. King read a paper *On Blight in Man, and the Animal and the Vegetable World.* Having defined the terms blight, contagion, and infection, the author proceeded to describe the signs by which their presence could be traced, and enumerated the various diseases which were supposed to be contagious or infectious, referring incidentally to small-pox, which could not, in his opinion, be averted by vaccination. He thought that disease was the result of a local impurity of the atmosphere, and that whereas a healthy person might be affected if he went to the locally impure spot, the party suffering could not convey it to another upon his removal to a different locality.

Dr. Hitchman read a paper on the *Anatomy of Intellect,* detailing numerous physiological experiments in regard to the nature of life and mind in man and animals. Mental phenomena, he maintained, did not always imply the existence of brain, or cephalic ganglia, or of nerves conveying impressions to cerebral organisation at all. Mind is not invariably dependent upon a molecular condition of brain—this organ being often sound in acute and chronic cases of insanity, the seat of disease being found, according to statistical observation, at home and abroad, in the alimentary canal, liver, uterus, spleen, heart, and lungs, in at least a moiety of all cases. This is true, even in the most severe mental affection known to the physician, paralytic dementia. The mental principle is not confined to brain molecules, but is equally contained in parts far distant from them, and is separable from the body, as mind, in a latent state, as well as an immaterial new individual. The whole mental organisation is specially operant independently of all molecular changes in ganglious and nervous cords, though the psychical mode of action is largely determined in the genus *homo* and higher forms of animal nature, by the modification of structure and physiological condition of each anatomical organ; both healthy and morbid changes show there is a certain point in the physical history of instinct and intelligence, at once and for ever fatal to the doctrine of Professor Tyndall, and other physicists, viz., that thought, sense, emotion, nay, every fact of consciousness, are due exclusively to molecular motions of brain.

On the Relation of the ancient Moabites to neighbouring Nations, as disclosed in the newly discovered Moabite Stone.—Rev. Dr. Ginsburgh. This stone was found as recently as the year 1868, during researches in Palestine; the inscription occupied 34 lines, and was written in a language which traced its origin to a date long prior to the Christian era. The translation looked like a chapter of the Bible; and when it was borne in mind that of 15 cities mentioned in the Old Testament, 11 were referred to on the stone, no one could doubt that the Moabites were in a far greater state of civilisation than was generally supposed. The inscription dated back as far as 900 years before Christ, and was, therefore, older than two-thirds of the Old Testament. As the result of careful study, he came to the conclusion that an organised Temple service was observed amongst the Jews out of Palestine, and that that service must have been very much akin to the service of the Moabites; that at a period 900 years before Christ, the word "Jehovah"—although subsequently avoided with so much persistency—was so often upon the lips of the Hebrew race, that it passed over to a neighbouring nation; that the simplicity of the language was a striking evidence of the advanced stage of civilisation of the Moabites, and that in prowess they were superior to the Jews.

The following papers were read relating to the Australians, their language, and mental characteristics. The first paper was by Mr. C. S. Wake, and was entitled, *The Physical Characteristics of the Australian Aborigines;* the second was sent by Dr. Bleek, and was on *The Position of Australian Languages.* The author traced certain analogies between the several Australian languages, placing them all in Max Müller's great nomadic or Turanian class; and although the Australians have, with few exceptions, no grammatical distinctions of gender, the author does not think that this necessarily excludes them from the sex-denoting family. The use of suffixes in the Australian languages led him to infer that they have been derived from the more temperate zones. Indeed, the nations using suffix-pronominal languages are found on the outskirts of the tropics, and in temperate and cold latitudes, while those speaking prefix-pronominal tongues are restricted to the tropics; and again, the suffix-pronominal class are addicted to sidereal worship, and the prefix-pronominal to ancestor worship. The author, however, carefully showed that the physical descent of a race by no means necessarily coincides with the descent of its language; and, in conclusion, the learned doctor expressed his belief, based on a study of the mythology and the present customs of the Australians, that these have degenerated from a higher state of civilisation. The third and concluding paper in this series was by Mr. C. S. Wake, and was on *The Mental Characteristics of the Australian Aborigines.*

Section G.—Mechanical Science

Rolling or Shaping Axles.—Mr. Alfred Bowater. This paper embraced a description of a new machine, existing in model, for the shaping of railway axles by rolling pressure. Whereas by the method of using the steam hammer an axle required half an hour in shaping, this rolling process would effect it in a superior manner in two minutes. The rolled axle was not only superior in quality, but was more uniform in size, and could be produced much more cheaply. The machine consisted of three rollers, which were regulated so that they might gradually press closer together, thus reducing the diameter of the bar and extending its length until shaped to the size required. Axles of any length could be rolled by the machine, with collars at any part of the tyre. The rollers were geared to revolve all in the same direction, and their friction imparted motion to the axle. The rolling process would obviate those flaws in axles which occasionally caused appalling accidents on railways.

On a New Safety Lamp.—Mr. W. E. Teale. After detailing a number of the objectionable features of the various safety lamps now in use, the author proceeded to say that, with a view to remedy so far as possible the dangers arising from the insecurity of the present oil lamps, the Protector Colliery Lamp has been carefully and thoughtfully designed to combine safety and brilliancy of light with cleanliness and economy. It is made on the principle of the ordinary sponge or portable gas lamp, in which is used a liquid specially prepared by the inventors. The reservoir, or gas-holder, is then screwed to the top of an ordinary Stephenson or Clanny lamp, within which are fixed a pair of horizontal hinges, moving upwards only. On the wick tube of the lamp, and sliding over it, is an outer tube, having round its centre a circular horizontal flange. When the reservoir is screwed upwards into the top, this flange comes into contact with the hinges, raises them in passing, and allows them to fall beneath it when screwed home, so that by reversing the screw, and withdrawing the reservoir gradually from the top, the said hinges prevent the return of the said sliding tube, thereby forcing it over the wick-tube, and so diminishing, and ultimately extinguishing the light. It is therefore impossible for a naked light to become exposed after the lamp has once been adjusted. To render security doubly sure, a lock and stop are so placed that after the light is put out by the action of the screw, it is still impossible for the collier to withdraw the reservoir from the top, so as to re-light his lamp. The safety of the mine is further insured by the fact that the gauze is kept perfectly clean, and therefore no coal-dust can adhere to it, as in the old oil lamps. In regulating and reducing the light when testing for gas, which can be done with the greatest ease and certainty, no pricker is used or required, and another source of danger is avoided. This lamp burns freely with less ventilation than any now in use, and is much more sensitive to the presence or action of gas, while it is impossible for the miner to light his pipe from, or tamper with, the light in any manner. It gives much more light than that produced by the very finest oil; and as neither smoke nor soot is made by combustion, the glass and gauze are as clean and the light as good at the end of the day as when the miner goes down the pit, and this without the trouble and great loss of time necessary to keep an oil lamp properly trimmed. As compared with oil, the cost of burning the Protector Colliery Lamp is very small, six days of ten hours each, or sixty hours, being obtained at a cost of threepence, or less than one half the price of ordinary miners' candles, and one-third that of the usual oil.

On Ocean Telegraphy.—Captain Rowett. The object aimed at in his paper by Captain Rowett was to show the superiority of hemp over metallic cables. The author contended that hemp cables were much lighter and extremely enduring when submerged, and iron cables were quickly corroded by the action of the sea water. Various specimens of submerged cable were exhibited by the author in support of his views.

SCIENTIFIC SERIALS

Journal of the Chemical Society, September, 1870.—This number only contains two papers; the first, on Vapour Densities, by Mr. J. T. Brown, contains a short description of the methods that have been proposed for their determination, and the formulæ employed for calculating the results from the data obtained. This serves as an introduction to a series of elaborate tables intended to facilitate these complicated calculations. The tables are a sequel to some previously published by Mr. Brown (*Journ. Chem. Soc.* N.S. iv. 72), and it might be acceptable to many chemists if the author would collect these and other tables and publish them in a separate pamphlet. The other paper is an abstract of a memoir in the Philosophical Transactions for 1869, entitled "Researches on Vanadium," by Professor Roscoe. The author has obtained three vanadium chlorides, a tetrachloride $V\,Cl_4$, a trichloride $V\,Cl_3$, and a dichloride $V\,Cl_2$. The tetrachloride may be prepared by passing dry chlorine over the mononitride heated to redness, or by transmitting a mixture of chlorine and the vapour of vanadyl trichloride $V\,O\,Cl_3$ over red-hot sugar-charcoal. Its vapour density corresponds to the formula $V\,Cl_4$. The trichloride is a crystalline peach-blossom coloured compound, resembling chromium sesquichloride. It is not volatile in hydrogen, but when strongly heated in this gas it loses chlorine, the dichloride and finally the metal being obtained. It is produced by heating the tetrachloride, or by its slow decomposition at the ordinary temperature, or by passing its vapour with hydrogen through a red-hot tube. Vanadium dichloride is an apple-green crystalline body, prepared by transmitting the vapour of the tetrachloride with hydrogen through a tube heated to dull redness. The dichloride, when heated in hydrogen in a platinum boat, yields the metal in bright, greyish-white lustrous grains. The processes hitherto described for the preparation of the metal have been tried by the author without success. The chloride or nitride is placed in a platinum boat and heated in a porcelain tube, through which a current of pure hydrogen passes. The metal does not tarnish in the air at common temperatures, but burns with brilliant scintillations when thrown into a flame. When heated in air it oxidises, producing all the oxides $V_2\,O$, $V_2\,O_2$, $V_2\,O_3$, $V_2\,O_4$, and $V_2\,O_5$. It is not attacked by hydrochloric acid or dilute sulphuric acid. Hot strong sulphuric acid slowly dissolves it. It is violently oxidised by nitric acid, and slowly dissolved by hydrofluoric. The metal burns in chlorine, and when heated in nitrogen forms the mononitride.

DIARY

THURSDAY, November 3.

Linnean Society, at 8.—On the Fertilisation of Orchids and Asclepiads: Dr. Mansel Weale.—On a Solitary Bee from South Africa: Dr. Mansel Weale.

Chemical Society, at 8.—On the Analysis of Cast-iron: Mr. A. H. Elliott.

MONDAY, November 7.

Royal Institution, at 2.—General Monthly Meeting.

London Institution, at 4.—Chemistry: Prof. Odling.

TUESDAY, November 8.

Ethnological Society, at 8.—On the Kimmerian and Atlantean Races: Mr. Hector McLean.—Note on the name "Aymara": Mr. C. R. Markham.—Reply to Mr. Markham's Note by Mr. David Forbes.

WEDNESDAY, November 9.

Royal Microscopical Society, at 8.—Notes on the Minute Structure of certain Insect Scales: Mr. S. J. M'Intire

THURSDAY, November 10.

London Mathematical Society, at 8.—General Meeting. Retiring President's Address. Sketch of recent researches upon quartic and quintic surfaces.

BOOKS RECEIVED

English.—The Elements of Mechanism: T. M. Goodeve (Longmans).—Papers on the Great Pyramid: J. V. Day (Edmonston and Douglas).

Foreign.—(Through Williams and Norgate)—Jahrbuch der Empfindungen: Hirzel und Gretschel.—Geometrische See-proben: Dr. Boetcher.—Ueber die Entwicklung und Verwendung der Wärme: P. Tunner.—Archiv für Ophthalmologie: Arlt, Donders, und von Graeffe.—Jahresbericht über die Fortschritte der Chemie.

CONTENTS

Errata.—Vol. ii., page 399, second column, line 18 from bottom, for "Electrometer" read "Anemometer." Page 512, second column, line 7 from bottom, for "requirements" read "acquirements."

NATURE

THURSDAY, NOVEMBER 10, 1870

SCIENCE AND THE WORKING CLASSES

THE spread of scientific instruction among the labouring population is a subject of greater importance than a superficial consideration might allow to it. Our scientific work is at present done almost entirely by our middle class, and mainly by those who have had such an education as is afforded by our universities or technical schools, or by foreign colleges. Not only do we look in this direction almost exclusively for the scientific training of the next generation, but also for the greater part of the work actually done in the field. Were statistics obtainable, it would surprise outsiders to learn how large a proportion of the practical observations in Astronomy, Geology, or Natural History is accomplished by men, the greater number of whose working hours are spent in towns or in some totally uncongenial occupation, and who can only devote a few precious hours stolen from their rest, or their brief summer holiday, to those pursuits which they have done so much to encourage.

This ought not so to be. Every one of these urban lovers of Nature must have returned from his annual retreat in the country with the thought how much more he could do for Science, how much greater scope he would find for the exercise of a keen eye or a cunning hand, if only fortune had so far favoured him that the prime of his life could be spent far from the tumult and dust of cities. And yet we find that, as a rule, those who do live in the country are very slow in making use of their glorious opportunities. The class who spend their whole time in the midst of every varying phase of the phenomena of Nature, have, taken as a whole, contributed little to the advancement of Science. How many a rare fossil, whose determination would have thrown light on some of the occult problems of geology, has been smashed by the careless hammer of the quarryman! How many a phenomenon of animal or vegetable life, the recording of which might have forestalled the discoveries of a Darwin or a Wallace by half a century, has remained unnoticed by the field-labourer before whose vacant gaze alone it passed! How many a strange monster or exquisite unknown form of life, for the possession of which all the museums of Europe would have eagerly competed, has been passed with merely an exclamation of awe or wonder by the untutored fisherman or sailor! The wealth of scientific knowledge which has in this manner been lost is incalculable. Now and then a Hugh Miller rises from the ranks to the command of a brigade in Science; now and then a George Stephenson, invincible from the feeling of conscious power, fights against difficulties of which those in the middle class can have but a faint conception, and comes to the fore by the force of inherent genius; but these are but a few solitary landmarks in the midst of the dead level of the intellects of our rural population.

The cause of this failure is not far to seek. It is simply want of education,—education, in the first place, of the powers of observation, and in the second place of the reasoning faculties, by the use of which alone the observations can be utilised and made to subserve the ends of Science. Everyone who has had the opportunity must have been struck with the dormant condition of the habist of observation of our agricultural population. An adaptation of purpose to end, or a deviation from the ordinary course of the laws of Nature, which would at once strike the educated eye, does not for a moment arrest their attention. Even of occurrences which pass daily before their eyes they are profoundly ignorant. We were once asked by a very intelligent labourer, whose occupation took him abroad frequently by night, if we could explain how it was that the moon shifted her place among the stars so much in the day time, while she remained stationary all night! The first thing to do with the working man is to teach him how to make use of his eyes. And in this first elementary lesson we are afraid our teachers of Science have hitherto lamentably failed. The error of "popular" scientific lectures, of evenings with working men at mechanics' institutes, is that which is so commonly attributed to clergymen, that of speaking over the heads of their audience. It does not really profit your Hodge or Styles to be discoursed to for an hour about the wonders of astronomy, the uninterrupted chain of organic beings from the Amœba to the Elephant, or the grandeur of the uniformitarian theory of geology. Take him out on a starry night and let him look through a telescope, and see for himself that Saturn is a round orb suspended in the air. with its marvellous rings and its attendant satellites; take him where with his own hands he may exhume a shark's tooth from a chalk-pit, and show him how this absolutely proves that the spot on which he stands was once fathoms deep beneath the ocean; put a flower in his hand, and point out the structure and the function of every organ, and you will at least have made a beginning. You cannot be too simple or practical. Treated in this way, we believe that every science-teacher who has tried the experiment will testify to the eagerness of the working man to increase his store of knowledge. In the case of those classes of the labouring population who live in towns, the only substitute is to take them to the Museums or Collections of Natural History, which are the best representatives of Nature herself. For our country gentlemen and tradesmen, the Naturalists' Field Clubs, which now flourish in so many counties, are doing a good work: something of a similar kind is wanted for the less educated class of the population.

But when the eye has been trained to observe, the whole work of education has by no means been accomplished. It is the portion of the work on which there is most need to insist at the present time, because it has hitherto been almost entirely neglected. The system pursued till recently in our Universities and public schools was based on a high cultivation of the reasoning faculties, to the almost entire exclusion of any recognition of the perceptive powers. There may be a danger now of running into the other extreme, and already we hear some zealous devotees of Natural Science exclaim against book knowledge, as if it were opposed to a practical scientific training. There cannot be a greater mistake. Unless a man thinks to live the life of a recluse, and to profit nothing by the labours of others in the same field, the greater part of his knowledge must always be derived from books. What we insist on is that the learner must be taught *first* to use his own eyes, before he has recourse to the experience of others. No man can be considered to be highly educated who does not possess the power of bringing his perceptive faculties to play on the phenomena that surround him, and also of exercising his reasoning powers to systematise his observations, and to compare them with those of others who have preceded him. The surest way of cultivating the Perception is by the severe study of some branch of Natural Science; the Reason is to be trained in the lecture-room and the study. Nature does not proceed on the principle of setting one of her gifts at variance with another; and so far from one of these sets of faculties being opposed to the other, neither can be cultivated to the full extent of the mental powers without the assistance of the other. No nation has distinguished itself by producing a greater number of keen and accurate observers of Nature than the Scotch, and none has set a higher value on the education that is derived from books. In the scientific education of the agricultural population of England, it will be found that the long disuse for generations of the reasoning powers is the greatest difficulty to be overcome. Although we do meet here and there with those who are more or less accurate observers of Nature, it is extremely rare to find one who has any power of forming a connected train of reasoning as the result of his observations.

We need but look around us on the events passing before our eyes on the Continent of Europe, to recognise the manner in which Education is proclaiming herself victorious along the whole line. As a nation, we are slow to learn. But that nation must indeed be both deaf and blind, which does not at the present time see the necessity of straining every nerve to redeem itself from the disgrace of ignorance. With our working classes taught to exercise those faculties which they all possess, but which so few know how to use, and thus trained to form the strength of the nation in all fresh advancements in Science and the Arts, England would quickly distance all competitors, and assume that position which it would now seem younger rivals are likely to snatch from her grasp.

HUXLEY'S LAY SERMONS

Lay Sermons, Addresses, and Reviews. By Thomas Henry Huxley, LL.D., F.R.S. (Macmillan and Co., 1870.)

IN this volume Professor Huxley has presented to the public a miscellaneous collection of essays, some didactic, some controversial, some addressed to a general audience, some to a special one, and composed at various times during a number of years extending from 1854 to within the last few months.

The subjects of which the Professor treats are as various as the occasions for which his papers were written and the audiences which he addresses, and, as may be easily believed, his essays are of very unequal value. But one great element of value they all possess in common, and that is, the thorough-going boldness, and honesty, and out-spokenness with which they deal with all subjects alike. This is no small merit in any writer, and it is an especially great one in a man occupying the position which is held by Professor Huxley. It is a remarkable condition of English society at the present time that a man who combines real scientific eminence with great general ability and special oratorical power, as Professor Huxley does, is made, with or without any consent of his own, into a kind of popular oracle. Like an oracle he is expected to have a response ready for any imaginable query, and like an oracle too he must find himself not unfrequently under special and strong temptation to "prophesy smooth things." Yet Mr. Huxley does not prophesy smooth things; on the contrary, he does not hesitate to put the most unpopular propositions in the plainest possible language when he sees that it is right to do so; and to say that a man—and that man a public teacher—lies under special temptation, and that he resists that temptation, is to say at once that his teaching must be worth listening to, and that even where we cannot accept his doctrines, we may still listen to them with advantage and gain instruction from them.

With one exception, the papers in this volume may be classed under three heads, viz.: Educational Essays, either theoretical or practical, which include Nos. 1, 3, 4, 5, 6, and 9: Scientific Controversy, consisting of Nos. 12 and 13, on the Origin of Species; and also 7, 8, and 14, of which the first is the famous "Essay on the Physical Basis of Life," and the other two are replies to the attacks made upon the former: Finally, Presidential Addresses to the Geological Society, Nos. 10 and 11, of which the latter might fairly come under our second heading, consisting as it does of a very able reply to Sir W. Thomson's strictures upon modern geology. The essay which will not come into any of these divisions is the shortest in the book; viz. that on "Emancipation, Black and White." We must however devote some space to it, since it appears to us to be almost the best reasoned and most temperate view of what its author calls the "irrepressible woman question" which we have yet seen, although we are not prepared to accept the author's conclusions without reserve. In this essay Mr. Huxley's allegiance to the facts of science comes into uncomfortable collision with his allegiance to the traditions of party. He comes before us in the character of an advanced Liberal, but he cannot forget that he is, before all things, a biologist; and the consequence very naturally is, that although he is prepared to support a policy of emancipation—apparently upon the general principle that *all* government is a mistake—yet he is compelled to admit that the arguments of *extreme* emancipationists are "to a great extent nonsensical." We are confident that this question is one which must be ultimately settled mainly upon physiological grounds, and it is just because the conventions of society very rightly do not admit of the full and fair discussion of those grounds before mixed audiences, that the extreme emancipationists have been enabled to obtain for their theory the amount of currency which has lately fallen to its lot. In the present instance, Mr. Huxley appears to have followed out his physiological argument with characteristic fairness *to a certain point*, and consequently sees that after all due emancipation, "Nature's old salique law will not be repealed, no change of dynasty will be effected;" and again, that "so long as potential motherhood is her lot, woman will be found to be fearfully weighted in the race of life." But why should Mr. Huxley halt at this admission? Why does not his Darwinian logic carry him on to its legitimate and necessary consequence? According to the law of natural selection, when once fairly engaged in the struggle for existence, no less a penalty than ultimate extinction awaits the weaker race. If the parallelism between a race and a sex can be maintained at all—and the parallelism is Mr. Huxley's, not ours—it plainly implies that, put into competition with man, woman must sooner or later cease to exist *as a competitor*, just as certainly as the black rat has been driven out before the *Mus decumanus*, or as, to adopt a different class of example, the handloom weavers have been driven from the market by machinery and steam. But while we thus doubt the wisdom, or indeed the possibility, of placing women on a level with men, and in competition with them, we would by no means therefore be understood to argue against giving them a liberal education or improving the law in regard to their property.

Passing on to consider for a short time the Educational essays, we need say but a very few words of the single specimen given of the writer's method in practical education, viz. the Lecture on a Piece of Chalk. It is certain to be well known to most of our readers. Those who do know it, for the most part recognise it as a model both in matter and in manner of what a single lecture ought to be; those who do not had better read it at once, for till they have so done they will have but an imperfect idea of such a model. The other educational essays, viz. the first six in the book (with the exception of the second) contain an exposition of the author's views on many of those points in the theory of education which are most keenly disputed at the present time, such as the value of natural science as contrasted with mathematics or philology as an instrument of education; that of the natural history sciences as contrasted with other branches of natural science, the method by which they should be taught, &c. Now it is only fair to admit that in all these matters Professor Huxley's addresses must be looked upon as the speeches of an advocate, and moreover of an advocate who feels that he carries the feeling of the public with him for the most part, but is by no means equally sure that he can overcome the prejudices of the jury. Still, considered as the speeches of an advocate, they are admirable, and it must be remembered that an advocate may prove his case, and this, we think, Mr. Huxley has in several instances done. In regard to the most important of the questions discussed, we are disposed to believe that any one of these three instruments of education may turn out a highly cultivated and thoroughly well educated man, provided the teacher knows how to teach and the learner presents good raw material upon which he may exercise his skill; but this by no means proves that they are all of equal value. One thing we can certainly say in regard to the classical education of our own day, that is to say, of the day of those who are the acting men of the present generation, viz., that, however well it may have served the turn of that small minority who were sure to make the best of any kind of education, and for whom, therefore, it is the least necessary to make provision, it has done nothing at all for the great majority of those who have been submitted to it. It is not too much to say, that out of the men who have gone from public schools to Oxford, and who have spent their whole lives between the ages of eight and twenty-two in learning Latin and Greek, not one in three could at the latter age read a Latin or Greek author with ease and intelligence. This may not in itself prove the case of science as an instrument of education, or even prove the inefficiency of classics; but at least it shows that classics have failed as a fact, and reduces us to this dilemma, that we must admit either that they are but a very imperfect means of education, or that the general standard of educability among young Englishmen is unaccountably low. One other alternative indeed remains, viz. the supposition that classics have been generally very badly taught, but this seems to us hardly tenable. It is difficult to believe that so much labour has been bestowed by so many good scholars as may be found amongst the schoolmasters of the last fifty years, upon the art of teaching classics, without the elements even of the art being discovered. At any rate reformers, or even revolutionists, in education may fairly argue, that what has not been done in so many years by a method which has had the whole field of the higher education to itself, is hardly likely to be effected by a persistent continuance in the same path. We are reminded of the physician of Laputa, of whom, when he had already almost killed his victim by his discipline, Gulliver says, "We left the doctor endeavouring to recover his patient *by the same operation*."

We have left ourselves no space in which to notice the remaining and more directly scientific portion of Professor Huxley's work. The book is not to be discussed fairly in the space at our disposal: it is, however, full of interest throughout, and we need perhaps the less regret that we are unable to direct our readers' attention to the remaining essays, inasmuch as they constitute that part of the work which deals with the scientific controversies of the day some of which have already been discussed in NATURE.

G. W. C.

FERNET'S ELEMENTARY PHYSICS

Traité de Physique Elémentaire. Par Ch. Drion et E. Fernet. Troisième Edition. (Paris: V. Masson et Fils. 1869.)

THE third edition of this well-known handbook of French physics deserves more than a casual notice. We are told in the preface that it has been entirely recast by the second of the two original authors, M. Fernet, a pupil of the lamented Verdet, who has caught something of the spirit of his master. There has been no teacher of physics in our time whose work has been, on the whole, comparable to that of Verdet. He has all the clearness of Tyndall; and, as almost all of his published lectures were delivered to audiences more strictly scientific than those to whom the famous books on Sound and Heat were originally presented, he is never diffuse. His arrangement of the essential points of his subject, and his grouping of the illustrative details and of the exceptions to the general principles which govern it, have scarcely been equalled even in France, which is the special country of precise and exhaustive exposition. It is high praise, therefore, to say of M. Fernet, that in parts his book recalls his master's method and style.

The treatment of mechanics which is common in this country places statics before dynamics. There is only one thing to be said in favour of this arrangement—that the idea which lies at the root of dynamics, that of change of rate of motion, is a little difficult for a beginner to catch, and it is very hard to get him to see how to express it in any but the simplest case. On the other hand, we have no clear notion of Force at all until we master it, and statics without that idea is a series of barren propositions, which stand to real life much in the same relation as a "uniform, weightless, perfectly rigid, straight rod" does to a real bar. M. Fernet accordingly places this conception at the commencement of his book, and we find the laws of uniformly accelerated motion given before the discussion of levers and centres of gravity.

It is extremely easy, and perhaps a little ungracious, to select for notice points the omission of which causes surprise even in an elementary work of 800 pages. The need of compression, which constrains an author who has to treat in one volume mechanics, hydrostatics, pneumatics, light, heat, sound, electricity, magnetism, and meteorology, is so great, that it is impossible to question too loudly the prudence of obvious omissions. But we should have expected to find a little discussion of the adhesion of liquid plates to the solids which they wet, and to each other, ; and one would willingly excuse the absence of the regulation picture of the balloon and its car, with the accompanying history of the brothers Montgolfier, for an account of the mercurial air-pump of Sprengel or Jolly. M. Fernet is perhaps a little open to the charge which is constantly brought against the scientific men of his country, that if they read anything but the science of the *Comptes Rendus* and the *Annales de Chimie et de Physique*, they never indicate the fact by a line or an allusion. M. Verdet alone, of well-known French scientific writers of our time, knew German and English as well as French science, and showed that he knew it. We should scarcely have found any book of his on the subject of heat, without any reference—as far, at least, as I can find—to Joule's principle of the equivalence of mechanical effect and heat, of the "mechanical equivalent" by which the one may be converted into the other, or of the fraction of the heat which can be converted into work by a perfect heat engine.

So far as it goes, in fact, the book is extremely clear and satisfactory; but it gives one less impression of a complete working up of the subject to the latest date than we had expected to find in it. Take for instance the well-known series of experiments by which Kundt established the velocity of sound in tubes of different materials. They were explained by Tyndall in this country a couple of years since, and it is impossible to conceive any which make more visible to the student those vibrations of bodies which he is constantly required to admit in the course of his reading on acoustics. The omission of all mention of the famous "singing flames" is more defensible from a purely scientific point of view, as the experiments scarcely admit precise measurements, and can only be relied on to convince any one who needs convincing how many astonishing things there are within the range of the science.

M. Fernet has given a considerable number of notes, in which there is a precise mathematical treatment of the statements in the text. We should be glad to see the plan followed more frequently in elementary treatises. In a book, the introduction of simple mathematics in a note does not distract the attention of the reader who is frightened even by a simple equation, and it gives precision to statements which can scarcely be fixed without them, or without a long and extremely tedious paraphrase. We are more doubtful of the advantage of a practice common in France, and which has crept into some English books; the introduction into the text of *notes non exigées*. These are parts which the student who is preparing for a special examination may omit if he chooses. The text of a book of this kind ought, it seems to us, to be either one thing or another—to be composed with a perfectly definite object, and to be one and indivisible. As it is, it produces something of the impression that is given occasionally when a single picture is used to illustrate two different propositions. The lines which belong to the first get so mixed with those of the second, that the student can follow neither. A book too full of *notes non exigées* is apt to be too little systematic and scientific for the more advanced student for whose benefit these notes are inserted, and to be made too difficult for the simpler readers whose wants are mainly kept in view.

WILLIAM JACK

OUR BOOKSHELF

Cryptogames Vasculaires du Brésil. Par Prof. A. L. Fée avec le concours de Monsieur le Dr. Glaziou. Pp. 268, 4to., 78 Plates. (Paris: Baillière.)

PROFESSOR FEE is by many years the oldest amongst living fern-authors. He has held for more than a quarter of a century the chair of botany at Strasburg, and has concentrated his attention principally upon ferns and the other allied higher orders of cryptogamic plants. He published a general treatise upon the classification of the order as long ago as 1844, and since then many consecutive years have never passed without producing some memoir upon the subject from his fertile pen. Having recently received a fine collection of ferns from Dr. Glaziou, the superintendent of the Botanic Gardens at Rio Janeiro, he has been stimulated to add one more memoir to the series, and that is the work now before us. All the series of his monographs, several of which are in folio, are illustrated beautifully and copiously, not only with full-sized figures of the plants, but also with careful magnified analytical details; and together they form by far the most extensive and excellent series of fern-plates which anyone upon the Continent has published. The present memoir is quite upon a par with its predecessors in this respect. It is in quarto, and contains seventy-eight quarto plates and a list of all the ferns and fern-allies known to the author as inhabiting Brazil, with a list of special stations, but with descriptions of novelties only. But there is one drawback to the value of Fée's works, and that is a very great one. Living at a distance from the great metropolitan herbaria, our author has apparently worked almost entirely upon his own private collections, and has continually failed to recognise well-known plants, and has made new species in great numbers out of the specimens which his correspondents have sent him, which no one else has been able to understand as such. In none of his works—we have no alternative but to say—has this tendency been carried to a greater excess than in the present one. For Brazil alone he describes and figures in the present memoir upwards of 180 new species, so called. These are not from tracts of country which the collectors whose gatherings have been already reported upon have not visited, or have left unexplored, but nearly all from the vicinity of the capital, and from the gatherings of Glaziou. Now the neighbourhood of Rio Janeiro is exceedingly rich in ferns; but there is, perhaps, no other part of Tropical America from which herbaria, both in England and on the Continent, have been more bountifully supplied. The consequence is, that out of this 180 we do not think that more than from twelve to twenty species are really new, in any sense in which we understand in this country what is meant by a species. For instance, we have some seven or eight species elaborately characterised and figured from what cannot be called anything else than so many individual fronds of that most cosmopolitan of ferns, our common English *Aspidium* or *Polystichum aculeatum*. Or, to take one of the exclusively Brazilian species, *Cyathea Gardneri*, a very distinct tree-fern, is included in the list under five different names—*Gardneri* (Dr. Gardner's number on which Hooker described the species quoted), *incurvata* (a name of Kunze's published in the Linnæa from Regnell's specimens), *mamillata*, *taunaysiana* and *attenuata*, the last three new species here named and figured for the first time; but the figures, beautiful as they are, might, any of them, have been drawn from Gardner's specimens. The author does not seem to have any knowledge of numerous English and German books and papers in which Tropical American ferns are described, as for instance, Grisebach's excellent Flora of the British West Indies; and this leads to further name-crossing. In short, although one cannot but admire the excellence and the copiousness of the illustrations in these memoirs, and ought not to leave out of sight the example of devotedness to science which they show, expenditure of time devoted to one object through a long course of years, and of money, only a very small proportion of which their sale can possibly repay, yet still the predominant feeling on the mind must needs be that to deal with plants in this way has a direct tendency to bring species-botany at a very rapid rate into a state of utter confusion.

J. G. BAKER

The Laboratory Guide. A Manual of Practical Chemistry for Colleges and Schools, especially arranged for Agricultural Students. By A. H. Church, M.A., Professor of Chemistry in the Royal Agricultural College, Cirencester. Second edition, enlarged and revised, pp. 170. (London: Van Voorst, 1870.)

THIS little book, as its title indicates, is intended mainly for the use of students of agricultural chemistry, and we fear it might cause disappointment to anyone who wished to employ it as a guide to general analysis. The science of chemistry is so rapidly increasing, that it would seem almost hopeless, at the present time, to give students a complete knowledge of chemistry and leave them to apply their information to the special subject they intend to follow. Professor Church's book is intended to obviate this difficulty, and after a few introductory lessons of universal application, the student commences experiments on materials with which he is certain to come in contact in agriculture, such as superphosphate, milk, soils, &c. Part I. treats of chemical manipulation, and consists of a number of lessons intended to accompany the course of lectures, and from which the student will learn the mode of performing some simple operations, as solution, filtration, crystallisation, specific gravity, and will become acquainted with the modes of preparation and properties of the principal elements and compounds. Each lesson commences with a list of the apparatus required, the ordinary reagents, and the special materials and tests necessary for the performance of the experiments, which are detailed with great clearness. This arrangement is calculated to cause the student to be careful to have everything ready before commencing work, and will thus save him much time and inconvenience, for few things are more likely to endanger the success of an experiment than leaving it at a critical moment in order to obtain some piece of apparatus or reagent which should have been previously prepared. Part II. treats of qualitative analysis, of which Chapter I. deals with the elements, reagents and tests, and reactions; and here we find the terms univinculant, bivinculant, trivinculant, &c., as equivalent to monad, dyad, triad, &c. The principal distinguishing characteristics of the different groups of elements are here given. The section on reagents and tests will be found useful, for it contains the modes of testing for impurities, and indicates the strength of the different solutions employed, two things to which attention should always be paid. The second chapter of this part describes the methods of qualitative analysis, all rare elements and those with which the agricultural student is not likely to meet being omitted. The third part is devoted to the general processes of quantitative analysis, and the fourth to the examination of manures, soils, water, and food. This book will doubtless be invaluable to agricultural students, besides being useful to those requiring special information on the subjects of which it treats. The appearance of such a work is a satisfactory indication of the extension of the application of scientific chemistry to the useful arts.

The Book of the Roach. By Greville Fennell (of the *Field*). 16mo. pp. 118. (London: Longmans and Co. 1870.)

WHILST Mr. Pennell has instructed us in catching *lege artis* all the various fish in British rivers and lakes, Mr. Fennell has been content to devote a little volume to the natural history and fishing of the Roach. Let no one smile at the man in the punt with his humble notions of enjoyment. Maybe he has been toiling hard the whole week in the noisy, murky town; the quiet sport of the Saturday afternoon suits his purse exactly, and there will be real enjoyment over the dish of fried roach "caught by father." Nay, if we could measure the amount of pleasure, healthy recreation, and renewal of vigour obtained by the multitude in the unpretentious sport of roach-fishing, and compare it with that sought for by the select few who have the privilege of finding their amusement on a salmon river, we should probably find the balance very much on the side of the former. No apology, therefore, was needed from Mr. Fennell for the publication of his little book on the Roach. He has divided it into eight chapters, of which the first two are devoted to the natural history of this fish, and the five following to a description of the tackle and various kinds of baits, and to the methods of roach-fishing generally as well as at certain localities. In the last chapter hints are given on the roach as an article of food, on the method of cooking, &c.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Hypothesis regarding the Corona

HAVING read in Nos. 34 and 35 of the valuable periodical NATURE (of June 23 and 30) the two articles about the Corona, I beg leave to direct your attention to an hypothesis concerning its nature, and especially the origin of the *beams*, which I sent to the Physical section of the Amsterdam Academy of Sciences, of which I have the honour to be a member.

I have just received No. 1776 of the *Astronomische Nachrichten*, for October 15, where the American astronomer, Dr. Gould, in a notice regarding the total eclipse of the sun of August 7 (1869) says:—

"Of the Corona I made some hasty measurements both with the telescope and without it. Its form varied continually, and I obtained drawings for three epochs at intervals of a minute. It was very irregular in form, and in no apparent relation with the protuberances of the sun, or the position of the moon. Indeed, there were many phenomena which would almost lead to the belief that it was an atmospheric rather than a cosmical phenomenon. One of the beams was at least 30′ long."

This passage induced me to submit to the trial and judgment of my fellow-members of the Physical section of the Royal Academy a very simple hypothesis regarding the nature of the Corona, which entered my mind shortly after the observation of the total eclipse of August 18, 1868.*

I think—and, if I am not mistaken, all astronomers agree with me—that a part of the luminous phenomenon which we call the Corona belongs to an atmosphere of the sun,† having a feeble reflecting power, or being itself luminous. But the beams in the Corona, whose variability is now confirmed anew, are necessarily an optical phenomenon. They originate, I believe, in the inequalities of the moon's surface. If the sunlight slants somewhere along the moon's limb through a *valley*, we observe from our point of view a *beam*, provided there exist between the moon and us particles able to reflect the sunlight, or to transmit it like semi-transparent bodies. There is no need to have recourse to diffraction.

To look for these particles in the atmosphere of the earth, as Mr. Gould does, is, in my opinion, not tenable, as the Corona and the beams have also been observed in eclipses, where the cone of the shadow even had‡ a breadth of thirty-six German leagues. The molecules of the atmosphere, which we see around the eclipsed sun, are wholly within the cone of the shadow.

These reflecting particles are undoubtedly to be looked for beyond our atmosphere, between the moon and the earth, and I believe that they may be regarded as identical with those particles which float in the ether, and under other circumstances cause the zodiacal light.

That the zodiacal light, or rather the particles which cause it, reach the earth's orbit, is, as regards nearly its whole circumference, not subject to any doubt, as the apex of the zodiacal light is "mostly farther off the sun than 90°. Only in the months of March and April is it not possible to follow the zodiacal light so far" (Schmidt, "Das Zodiacallicht," Braunschweig, 1856). But then, at those particles which are situated on the apex of the zodiacal light, the sun's ray makes a right angle with the line which joins the earth, and the circumstances are not favourable for small and widely-dispersed particles to reflect much sunlight in the direction of the earth. It is, therefore, probable that in March and April these particles would show themselves farther from the sun if the illumination were stronger. At a total eclipse of the sun that angle is $179\frac{1}{4}°$ for a particle visible at 30′ distance from the moon's limb, and $179\frac{3}{4}°$ for particles in the immediate neighbourhood of the moon's limb; and it is an acknowledged fact that, under these circumstances, there is much more light reflected than if reflected at a right angle. Moreover, the intensity of the transmitted light increases equally with this angle.

Schmidt mentions, in his above-quoted work, that he and other observers, during the total eclipse of July 28, 1857, looked out for the zodiacal light, but in vain. He thought the sky not dark enough, and expresses himself as follows:—"Das Ansehen der den schwarzen Mond umgebenden vielstrahligen Corona war im ganzen betrachtet nicht gerade geeignet, sie *sogleich* in Beziehung zum Zodiacallichte zu denken."

Thus it seems that the beams made Schmidt conclude, "This is no zodiacal light." If my explanation is the true one, and if the sun's atmosphere is accepted as unlimited, and gradually passing over into the ether, then the light of the Corona, which equally surrounds the moon, falls altogether into the same category as the beams, only that it originates in the reflecting particles beyond the moon. Accordingly, my hypothesis is expressed thus: *Both the Corona and its beams have the same origin as the zodiacal light.*

I remark, finally, that the strangely curved form of some beams, as well as their variability, may be very well accounted for on this hypothesis—the curved form by the irregularity of the moon's surface. For instance: I take a particle of light of a beam of the Corona; I imagine myself in the molecule which, according to my hypothesis, corresponds with that particle of light, and which is situated between the moon and my eye. Looking, then, from that stand-point to the moon, I must see the light of the sun slanting over a valley; but if I move myself laterally—*i.e.* in the direction parallel to the moon's radius which corresponds with that valley—then it is not certain that I shall see on the same point an extraordinary amount of light, for it is possible that at the same place a ridge has intervened. It is, however, very possible that, if I move in a direction perpendicular to the former (and also perpendicular to the direction towards the earth), I come into a region where that ridge does not intervene, but where the continuation of the valley is again visible, through which the sunlight slants. In this case, the beam of the Corona—*i.e.* the effect produced by those particles which receive more light than others at equal distances from the surface of the cone, having its apex in the eye, and which surrounds the moon—has a curved form.

The variability is, I think, satisfactorily explained by the motion of the moon passing by the sun.

This hypothesis forced itself upon me when at Toli-holi* I saw the moon rising behind a hill. Before she made her appearance her light shone over the trees, and produced, in a hazy air on my side of the hill, beams which very much resembled those of the Corona. I do not know whether the zodiacal light has already been analysed by the spectroscope; if so, the comparison of the spectra of zodiacal light and the Corona will serve to test my hypothesis.

A second test is this: total eclipses observed in the months of December and January should show less brilliant beams than total eclipses observed in other months, since in December and January the earth is near the direction of the perihelion of the circumference of the zodiacal light. The next total eclipse of December 12, 1871, will perhaps give some information on this point.†

The Fuel of the Sun

IN your impression of October 6 Mr. Murphy adds another to the frequent attempts that are still made to galvanise the expiring hypothesis that attributes the solar heat and light to a meteoric bombardment. Many very strong and sufficient objections have been already brought against it, but as Mr. Murphy states that he is "not mathematician enough to form any opinion on the merits of the controversy," I will add two arguments which to my mind are quite sufficient to annihilate this explanation—both of which may be sufficiently understood without mathematics, and neither of which have I ever seen fairly stated.

1st. The advocates of the meteoric bombardment usually start from the fact that great meteoric showers fall upon the earth. Thus, Dr. Tyndall, in his lectures on "Heat considered as a Mode of Motion," introduces Mayer's hypotheses, with an account of the number of meteors counted during the August and November showers; and these observed meteors and a few comets are the only actual observed material upon which this bombardment theory rests—all beyond them are mere figments of mathematical imagination, and any supplies derived from the zodiacal light, or otherwise exclusively from the space within the earth's orbit, must have been exhausted within the period of human existence.

Now, it is quite obvious, without any detailed calculation, that if these meteoric bodies, coming from anywhere you please outside of the earth's orbit in sufficient quantities to maintain the heat and light of the sun, had fallen, as they must have done, upon the earth in a proportion due to its magnitude and position, they must in the course of a few millions of years—say from the era of the Laurentian rocks to that of the London sewage deposits—have covered the earth with a very important superficial stratum, instead of merely supplying a few rare specimens for our museums. Every slowly deposited sedimentary rock upon the face of the earth should be thickly peppered and conglomerated with meteoric dust and nodules. With these considerations and the well-known geological facts before us, I need scarcely state the obvious conclusion, viz. that the evidences in support of the theoretical terrestrial requirements of this bombardment hypothesis are contemptibly insufficient.

My second objection attacks the fundamental basis of this hypothesis, and I think destroys it altogether. I maintain that any explanation of the sources of solar light and heat which does not equally and necessarily account for the radiations of all the other self-luminous orbs that people the whole immeasurable depths of space, is philosophically worthless. It is thus worthless if it does not also account for the perpetual renewal, the constancy, the eternal permanence, of all these radiations. The pale nebulæ, as well as the brighter suns, should be equally included in its grasp.

Tested thus broadly and philosophically, the meteoric bombardment hypothesis appears in its true colours as a monstrous physical absurdity. It assumes a perpetual flow of solid masses *converging* continuously from everywhere towards everywhere; or otherwise a state of things which could only endure through the time which these meteoric masses would occupy in travelling the semi-distance between the neighbouring suns. These little journeys ended, the interstellar space must, according to this hypothesis, become a sterile vacuum, all the lights of heaven must go out, eternal darkness must rest upon the face of the deep, and everlasting death pervade the universe.

W. MATTIEU WILLIAMS

The Cockroach

I HAVE only to-day noticed the Rev. C. J. Robinson's letter on this subject in your issue of the 29th Sept. A friend of mine, whom I have known all my life, who occupied an important trust as Bank Manager in India last year, and who is at present home on sick leave, assures me that Dr. Norman Macleod is wrong when he denies the nail-nibbling propensities of the cockroach. My friend had been in Kurachee for some time, and on his journey from that town to Bombay by sea he was annoyed one night in his berth by some insect crawling over his face; half asleep and half awake he put up his hand to his face and sent the insect to the foot of his berth. Shortly after he was awoke by a pain at his great toe, and on looking at it he discovered that a cockroach had nibbled off all the nail down to the quick.

JAMES DURIE

Aberystwith, Oct. 8

Were Cockroaches known to the Ancient Greeks and Romans?

YOUR correspondent, Rev. C. J. Robinson, drew attention in your columns (NATURE, Sept. 29) to the question whether these troublesome insects were known to the Ancient Greeks and Romans; he says, "there is a good deal to lead one to suppose that the μυλακρίs mentioned by Aristotle, and the *Blatta pistrinorum* of Latin writers was the same as our loathsome pest." I think Mr. Robinson is mistaken in supposing that the μυλακρίs is mentioned by Aristotle, at least I can find no mention made of this insect in the writings of the Stagirite. The word μυλακρίs, meaning some kind of insect, occurs in the fragments of Aristophanes preserved by Pollux, who amongst other meanings of the term gives the following one:—*ζῶόν η ἐν τῷ μύλωνι γινόμενον*, and then quotes this couplet from Aristophanes,

῞Ινα ξυνῶσιν ᾧπερ ἥδεσθον βίῳ,
Σκώληκας ἐσθίοντες, καὶ μυλακρίδας.

"where they may partake of the food of which they are fond, eating worms and *mylacrides*." It would not be possible to say what the μυλακρίs here denotes, but from the creature being often produced in mills, it may possibly mean a "Cockroach," though a "meal-worm" (*i.e.*, the larva of the beetle, *Tenebrio mulitor*) would suit equally well. The Greeks, however, had a word which may well represent the Cockroach, though it is even here impossible to speak with certainty. The word, σίλφη, it is probable denotes this insect. Aristotle (Hist. Anim. viii. 19. § 4) uses the word once; he enumerates the *silphe* amongst insects which cast their skins. The Scholiast in the "Peace" of Aristophanes says the *silphe* is an ill-smelling insect (δυσώδμος). Aetius (8. 33.) speaks of "the fat of the stinking *silphe* which inhabits houses." The epigrammatist Evenus (Analect, i. p. 167) speaks of the *silphe* of the booksellers' shops, and applies to it the epithets, page eating (σελιδηφάγος), destructive (λωβήτειρα), black-bodied (μελαινόχρως)." Lucian speaks of the mere book collector as providing pastime for mice and habitations for *silphe*, and cuffs his slaves for not keeping the mice and *silphe* away. (Advers. Indoct, iii. 114, Ed. Hemsterhus). The Scholiast here gives a description of the *silphe* which Schneider with some reason refers to some kind of *Lepisma*. Ælian (H. A. i. 37) says that the *silphe* infest swallows' nests; these cannot be cockroaches. Galen and Paulus Aegineta apply the epithet, βδέουσαι, to the *silphai*. Dioscorides (ii. 38) says that the inside of the *silphe* found in bake-houses when pounded with oil is good for pains in the ear. This leads me to the *Blatta* of the Romans. "On pulling off," says Pliny, "the head of a *blatta* it gives forth a greasy substance, which, beaten up with oil of roses, is said to be wonderfully good for affections of the ears." He speaks of the disgusting nature of this insect, one kind of which is known by the name of *Myloecon*, and found in mills (Nat. Hist. xxix. 39). In another place (xi. 34) Pliny says, "It is the nature of the *blatta* to seek dark corners and to avoid the light; they are very often found in baths." According to Virgil, "the light-avoiding *blattæ*" find their way into bee-hives (Geor. iv. 243). Horace (Sat. ii. 3, 119) ridicules an old miser for sleeping on straw and leaving his bed clothes in his chest, the food of *blattæ* and *tineæ*, "Blattarum ac tinearum Epulæ." Martial (Lib. iv. Ep. 37.) says unless his books are well put together they become the prey of *tineæ* and *blattæ*.

Constrictos nisi das mihi libellos
Admittam tineas trucesque blattas.

From the above passages it will be seen that the *blatta* was a destructive insect to clothes, books, &c., that it avoided the light, and was fond of warm places, that it frequented mills and exuded a greasy substance from its head, that it was a disgusting creature (probably in allusion to the smell) all of which particulars are true of cockroaches, and as there are many species of the family, and are widely distributed over all parts of the globe and must have been known to the ancients, I think there is good reason for concluding that the cockroach was known to the Greeks by the name of σίλφη, and to the Romans by that of *blatat.*

W. HOUGHTON

The Aurora Borealis

I SHALL be obliged if you will put on record a few scattered notes which I took of the splendid Aurora Borealis of October 25, seen from Arthingworth, Northamptonshire. When I first observed it at half-past five P.M., a crimson glow extended in an irregular band from N.N.E. to W., most prominent at about 20° to 30° above the horizon. This increased in height and breadth until it nearly reached a point S.W. of the zenith, and about 15° W.N.W. of the star Vega. At this time the northern part of the sky was perfectly free from aurora; gradually that part and the whole dome of the heavens, with the exception of a section from W. to nearly S., became filled with luminous streamers. These, for about 20° on each side of N., were white, the others crimson striped with white or rather greenish light, but the green I believe to be an effect of contrast, as where similar streamers were distant from the red light they were white.

The white or green steamers appeared to eclipse the red light, they changed their size, shape, and position, while the red continued comparatively unchanged. There were also dark streamers which, at first, I believed to be mere spaces without light, and to be caused by the darkness beyond, but I became ultimately convinced (as far as one could be convinced by appearances so subject to illusion) that they formed a part of the phenomenon itself. These streamers or long brushes could be seen beyond and clear of the luminous portion of the aurora, leaving the normal light of the sky between them and it, and hanging like long horse-tails, or like the fringes of rain seen on the edges of a distant rain cloud; changing their shape and position just as the luminous streamers are seen to do.

The most remarkable part of the phenomenon, however, was the circle of sky, or what may be called the pole of the aurora, to which the streamers converged. It appeared to embrace about from 7° to 10° of space. To an ordinary observer it might have appeared occasionally to shift its position to some extent, but, as far as I could judge during an hour's observations, this was not really the case, flickerings at times covered portions of it, and at other times the whole became faintly luminous; but by marking its position with reference to some small stars, this seemed to me to be unaltered. Most singular were the terminations of the streamers they culminated at this circle, not being undefined or gradually evanescent, but having angular tips far brighter than the portions immediately beneath, the nearest illustration to which I can give is an inverted fish-tail or batswing gas burner, except that this gives a feeble light at the point, while the aurora tips were whitest and brightest there, the streamers now fading off, and now becoming brighter and tinged with red as they got to 40° or 50° from the horizon; the tips varied constantly, but preserved the mean distance from the pole or focus of the aurora. The position of this was, as far as I could ascertain without star maps or instruments for observation, about 15° W.N.W. of Vega. The convergence of the beams was not in appearance conical, but dome or cupola shaped; this was, however, in all probability an optical illusion. Whether there was really a convergence or whether the beams were parallel, and the convergence an effect of perspective, can only be decided if some approximative measures of the distance of the streamers be ascertained. It appears to have been at a greater distance from the earth than is usually attributed to aurora borealis, having been seen in different parts of Europe and I believe in America. Doubtless the comparison of these observations will give some parallax or approximation to measurement of the distance. I remember about seven or eight years ago seeing an aurora at Chester, where the flashes appeared close to the observer, so that gleams of light continuous with the streamers could be seen between the houses of the town and myself, like the portions of a rainbow intervening between terrestrial objects and the observer. I tried then to ascertain if there was any reflection or other cause of optical illusion, but could not see it as other than a real effect; I seemed, so to speak, to be in the aurora. The effect on the 25th was very different, and gave me the idea of great distance.

The light was sufficient to enable me to tell the time by my watch easily, but not to read newspaper print.

Between half-past six and seven o'clock it faded away, and at from half-past seven to ten had become an ordinary white aurora, confined to the northern portion of the heavens.

115, Harley Street, Nov. 2 W. R. GROVE

ON the evening of the 24th ult. the aurora was most beautifully seen here, and if you have space for it, I will add a further spectroscopic observation to those you have already recorded. I found no continuous spectrum, but two of the lines described by your other correspondent.

1. A line in the light green, much reminding one of the line from the larger nebulæ, but more brilliant and with a peculiar flickering in it. This line was well seen in all parts of the sky, but was specially bright in the auroral patches of silver light.

2. A line in the red, very much like the lithium line, but rather more dusky. This line was only well seen in the rosy patches of the aurora, but could be faintly traced wherever the rose tint at all extended.

When the display of rose-coloured light was at its height, the spectrum from the most vividly coloured portion gave the red line very distinct, while the green line still remained bright by its side. I am quite inclined to agree with your correspondent, T.F., in the conjecture that both these lines are due to hydrogen, though (probably through difference in temperature or pressure) they do not quite agree with the lines of that gas as taken from the discharge in a vacuum tube.

The spectroscope was one of Mr. Browning's small direct-vision 5-prism instruments adapted for star purposes.

It may be worthy of note that the belts of Jupiter are highly coloured at the present time. The equatorial zone is of a distinct dark ochre colour, deepening to red brown as it approaches the lower edge (in an inverting telescope); two thin belts above are slate purple, and a darker belt below is of a deep purple, with a faint trace of rose colour.

The planet was thus seen on Nov. 2, at 9 p.m., not far above the horizon, and in bright moonlight, in a 8½ Browning's silvered spectrum with achromatic eye-pieces—144, 305, and 450; best I think with 144.

Guildford, Nov. 5 J. R. CAPRON

Clouds

I DO not think Prof. Poey's "New Classification of Clouds," published in NATURE of Sept. 8th, does much to advance science. I see no use in any classification of clouds, unless it is based on their mode of formation, and, so far as I see, there are but three ways in which it is possible for clouds to be formed. These are:—

1. The cooling of a mass of air *in situ* by radiation. This forms stratus.

2. The cooling of a mass of air by diminished pressure when it flows in an ascending column. This forms cumulus. A modification of this process is when (according to Espy) sudden expansion takes place above, so as to diminish the pressure through the entire height of a column of air, and, in consequence of the cold due to the diminution of pressure, to produce condensation of vapour throughout the column. This is Espy's explanation of waterspouts.

3. The cooling of a mass of air by coming into contact with a cooler mass of air than itself. This forms cirrus.

Of course these three modes of formation may be modified and combined in endless ways. To mention one of the simplest: A cloud which has begun to form as a cirrus or cumulus, may become a centre from which heat is radiated, and thus go on forming as a stratus.

It is in the highest degree unphilosophical to reject stratus as a species of cloud on the ground that it is "not a cloud properly so called, but a mist or hoar frost." A cloud and a mist do not differ fundamentally.

Prof. Poey is, however, right in saying that cumulus is not a distinct species of cloud. It is only a cloud which (in consequence, I believe, of the loss of electrical tension) has begun to run together into raindrops. JOSEPH JOHN MURPHY

Old Forge, Dunmurry, Co. Antrim

Extreme Seasons

A GREAT deal of speculation has been indulged in to account for the extreme seasons that have prevailed over so large a part of the northern hemisphere during the last few months. In this country, as we are subject to extreme seasons, more particularly as regards the rainfall, the subject is one of peculiar interest. In a paper read before the California Academy of Sciences in February on the subject of our extreme seasons, I brought forward a number of observations to show that these were due to broad polar and equatorial currents occupying large portions of the earth's surface continuously, and without much perpendicular or horizontal disturbance, except at the borders where the currents meet. The facts I then brought forward showed that from October to the middle of February a northerly current prevails over this portion of the American continent, extending from one to two hundred miles to the westward of San Francisco to the eastern edge of the Mississippi valley, whilst a southerly current prevails over the eastern side of the continent as far as the Atlantic. The southerly current to the westward extends uninterruptedly across the whole breadth of the Pacific to the coast of Japan. This same distribution of air currents without much perpendicular or horizontal mixing has apparently continued during the summer, and acounts, I think, satisfactorily for the extreme heat that has marked the continental climates over so large a part of the northern hemisphere. Nor is it surprising that the summer temperature on the continents should be so universally hot, as a horizontal wind, either from the north or from the south, blowing over the land in summer must necessarily be a hot wind. That there is no cosmical cause for this elevated temperature is proved by the extremely low summer temperature prevailing over the Pacific between this place and Japan. The mean temperature, as ascertained by observations made on board the mail steamships between here and Japan was, for Nov. 1869, $70^\circ{\cdot}2$, for January, $62^\circ{\cdot}9$, for May, 1870, $61{\cdot}9$, for July, $65{\cdot}7$, giving a mean of $2^\circ{\cdot}7$ less for May and July than for January and February. The difference in favour of the winter temperature would be still more marked were the coast temperatures eliminated, as they perhaps should be; as these were much above the mean in summer and below the mean in winter. As to the causes that lead to the peculiar distribution of the air currents in certain seasons, I have not the slightest idea, but I think that, admitting the fact, it affords a satisfactory explanation of anomalous temperatures both in winter and summer.

San Francisco, California, Sept. 4 JAMES BLAKE

Cyclones

CYCLONES are commonly regarded as exceptional phenomena of the atmospheric circulation; and we see in text-books statements as to the seasons of the year at which they are most apt to occur, descriptions of the premonitory signs which herald their approach, and directions to aid ships in avoiding the most dangerous portions of the storm-field. In short, each cyclone is regarded as an exceptional fact, an isolated burst of fury from the old storm-god Hurakan.

The writer has lived all his life on the great highway of cyclones, at Charleston, South Carolina; and from the observations of many years, has been led to conclude that this commonly received view embraces only those cyclones which, on account of their rotatory violence, really do threaten destruction on land and sea; and that consequently it overlooks a most important series of phenomena, which, though they do not so forcibly arrest attention, are even perhaps more significant in a scientific point of view. Though *destructive cyclones* or hurricanes are ortunately rare, cyclones or grand rotatory movements of the atmosphere are, at least on certain portions of the earth's surface, of *every-day occurrence.* In Charleston, Savannah, and along the coast of South Carolina generally, the writer knows from experience that very few, if any, changes of wind are to be observed, but such as are due to the cyclone which happens just then to be passing on its northward journey; and even the apparent exceptions are probably not difficult of explanation.

There is in short an atmospheric "Gulf Stream," whose course, beginning somewhere eastward of the Caribbean Sea, is nearly the same as that of the oceanic "Gulf Stream," and this atmospheric stream is composed of an endless succession of cyclones chasing each other ceaselessly up towards the polar regions, along the track recognised as that of great hurricanes. These cyclones vary within very wide limits both as to velocity of rotation and velocity of translation, as well as in diameter, and all the characters usually ascribed to such atmospheric movements. Many of them exhibit no wind stronger than a pleasant breeze in any part of their field; and a few have so gentle a motion, at least in some parts of their circuit, as will not agitate an ordinary vane; a few are almost wholly without clouds, and very many wholly without rain or lightning. Their effect upon the barometer, when appreciable, must generally be very slight; but in temperature they are usually divided into a warm and a cool semicircle by a line which, in Charleston, lies about S. W. and N. E.

Observation of the winds, during a voyage in a sailing vessel from Charleston to Liverpool, along the course of the Gulf Stream, has satisfied the writer that this *stream* continues unbroken between these two points, and this conclusion was strengthened by repeating these observations between Liverpool and New York. In the former voyage, hardly one of the cyclones which passed over gave more than a stiff breeze, while in the latter, from Cape Clear to Sandy Hook, every cyclone was a storm, and one of them was reported by the captain, on his arrival, as a "hurricane."

The causes of this aërial current, and its connection with the circulation of the whole terrestrial atmosphere, it is not the writer's purpose at present to discuss, though he considers the discussion one of almost *cosmical* importance. But the existence of such a stream is a fact of practical commercial value, in fixing the natural highways for sailing vessels between Liverpool and the Atlantic and Gulf ports of the Southern States. Obviously the short route from Northern Europe to those ports will be that southward along the coast of Europe until reaching the trade winds, then westward to strike the cyclonic current in the neighbourhood of the West Indies, and then, if bound to Atlantic ports, northwestward with that current. When bound, on the contrary, from the Southern ports to Northern Europe, the short route is obviously that along the Gulf Stream, which is also that with the current of the atmospheric stream. To reverse this practice, either way, is deliberately to sail "against wind and tide," if such a stream exist.

The flow of atmospheric *waves* which, in a recent work, has been described as setting from the coast of America towards Europe, though the writer has not seen that work, he believes cannot be other than the flow of cyclones in that portion of the atmospheric stream lying between the vicinity of New York and the English Channel. The cyclonic character is not always distinct, and sometimes is completely masked by the great distance of the observer from the centre, and the consequent apparently rectilinear course of the wind; and the chances of mistake are still further increased when the observer is moving in a course parallel to the path of the centre of the cyclone.

These observations have already been brought to the notice of the Smithsonian Institution, and the writer hopes that something will be done in America towards the comprehensive, precise, and detailed inquiry which the subject demands. But unless attention of the same kind be given in Great Britain, and in the voyages of the Atlantic steamships, the resulting information will remain incomplete. JOHN M. CRADY

Curator of the Museum of the College of Charleston

Charleston, U.S., Sept. 13

Singing of Swans

IN times ancient and modern "singing of swans" has been reckoned by naturalists among "vulgar errors" and groundless superstitions. It may therefore be interesting to your readers to hear that swans actually do sing, which I can testify by my own personal experience.

From my ninth to my eighteenth year I lived at a place in the west of Iceland, called Gufudalur. It is situated at the end of a small firth, called Gufufjördur, which is so shallow that by low water it is almost dry: the bottom of the firth is covered with sea-grass (marhálmur). In this firth hundreds of swans gather together all the year round, except during the winter months, when the firth is covered with ice; and in the month of August, which is their moulting season, when all of them leave this firth and go to another not far off, called Gilsfjördur. There is no apparent reason for this migration, as Gufufjördur seems in every way as safe and convenient for them during this season as Gilsfjördur. Tradition therefore accounts for this migration in the following manner:—Once upon a time two widows lived one on each side of Gufufjördur. At that time the swans did not go away during the moulting season, and the widows used to gather great quantities of swans' feathers, which are sold in Iceland at the present day at a halfpenny a piece. Thus the swans' feathers formed a considerable item in the income of the two widows. Once, however, one of the widows gathered feathers on a piece of land belonging to the other. A quarrel arose, and one of the widows uttered a spell to the effect that henceforth all the swans should leave Gufufjördur during the moulting season. I will not vouch for the correctness of this tradition, but the fact remains that this migration takes place annually during the above-mentioned season.

During nine years I have heard the singing of the hundreds of swans which gather together in Gufufjördur. In the morning and evening their singing is so loud that it can be heard miles away, and the mountains on both sides ring with the echo of it, for at that time every individual swan seems to join in the chorus. This is, indeed, a wonderful concert. The singing of the swan has not the least resemblance to the cackling of geese or the quacking of ducks. In fact, its voice is unlike the voice of any other bird that I have heard; it seems so clear and full, and has, as it were, a metallic ring in it. When it is calm and clear in the morning or the evening, the swans fly along the valley towards the mountains in parties of seven or nine, sometimes only three; as far as I can remember they are always in odd numbers. During their flight, they either keep in a straight line, one after another, or they form a triangle, leaving an open space in the middle: the foremost swan sometimes emitting single sounds at short intervals. The tradition of the singing of the swan being sweetest just before its death is well known in Iceland; but I am unable either to deny or to confirm this tradition, because I have never been present at the death of a swan.

The swans of Gufufjördur do not lay eggs there, and I am inclined to think that the most of them do not lay eggs at all, for their number in this firth does not seem to be less from the middle of May to the end of July, which is the season during which swans in Iceland lay eggs and bring up their young ones. On the mountains round Gufufjördur there are many small lakes or tarns, and on the banks of those lakes I have seen swans build nests and lay eggs; as a rule there is only one pair on each lake, and, strange to say, these swans sing but very seldom.

State Aid to Science

I REGRET that I should have worded my lecture on Cosmical Physics in such a way as to leave it doubtful how the central establishment I spoke of was to be supported.

Unable myself to conceive the possibility of such an institution being properly supported otherwise than by State aid, I fear I did not sufficiently realise that others might not be of the same opinion. At the time of the establishment of the present Meteorological Office, it was acknowledged that private scientific enterprise cannot be expected to furnish the money requisite to carry on an extensive system of meteorological observations, and the same conclusion equally applies to the other branches of cosmical inquiry.

The most convincing proof of the justice of this conclusion lies in the fact that the British Association, who have hitherto contributed a large portion of their income to advance terrestrial magnetism, find that they cannot do so much longer without detriment to other subjects which have an equal claim upon their liberality. They have therefore resolved to give up their connection with the Kew Observatory after the autumn of 1872. Further proof is surely needless. B. STEWART

THE THEORY OF NATURAL SELECTION FROM A MATHEMATICAL POINT OF VIEW*

THE fascinating hypothesis of Darwinism has, within the last few years, so completely taken hold of the scientific mind, both in this country and in Germany, that almost the whole of our rising men of science may be classed as belonging to this school of thought. Probably since the time of Newton no man has had so great an influence over the development of scientific thought as Mr. Darwin; and no one can over-estimate the debt which Science owes to his patient researches and his clear insight into some of the hidden ways of Nature. The advocates of Darwinism have, however, almost invariably failed to recognise that the theory consists of two essentially distinct portions, one of which may be admitted while the other is denied. The first portion is that with which the name of Darwin is popularly associated, although its origination is by no means due to him, namely, the probable ancestry of all forms of living organism from a single or a few original germs; the other portion, and that which we especially owe to his genius, is the theory that the infinite modifications of existing forms owe their origin to a process of Natural Selection from spontaneous variations. These two perfectly distinct hypotheses have generally been so confounded together that those who have attacked or defended the one have also attacked or defended the other. My object in the present paper is to show that, while the former hypothesis may be considered as established, as nearly as it is possible to establish a theory which requires thousands or millions of years for its complete development, the arguments in support of the second hypothesis are far less satisfactory.

The principle that new forms of organic life have been produced by modifications of older nearly-allied forms is by no means a new one; its inherent reasonableness and probability commended it to Lamarck and the author of the "Vestiges of Creation" long before it was elaborated in a more scientific form by Mr. Darwin and Mr. Wallace. It has been opposed, of course, by theologians; but, were it not that the theological mind is inherently averse to the reception of new ideas, it would have been seen that the supposition that the Creative Power works by continuous modification and adaptation of contrivance to end, by a constant exercise of His prerogative, is a far higher tribute to His exalted attributes, than the popular dogma that all living things were created as we now see them by one single gigantic effort, after which the power collapsed, and has never since been exercised. Why should organic life be the one thing in the world not subject to change? The *coup de grace* may be considered to have been given to the anciently received theory by the investigations so ably carried out by Mr. Darwin and Dr. Hooker on the characteristics of Insular Floras. The fact that no island which has been separated from the mainland during recent geological epochs has genera, and scarcely even species, of animals or plants peculiar to itself, while islands which have remained isolated during lengthened geological periods have faunæ and floræ almost entirely peculiar to themselves, is inexplicable on any other hypothesis than that of the gradual differentiation of species by long-continued separation. No more striking instance of this law has been given than that afforded by the East Indian Islands, as shown in Mr. Wallace's "Malay Archipelago." Two great types of animals and plants are found in different regions of the archipelago, the Indo-Malayan and the Australian; and these two types are separated, not by any diversity of climate and soil—not even by any of the wide but shallow channels which indicate recent separation, such as that between Borneo and Sumatra—but by the narrow but very deep channel separating Bali from Lombok, which indicates a lengthened geological separation of two continents at this point.

The hypothesis that the prime agent in all these infinite modifications is the principle of Natural Selection from spontaneous variations, has been recently further illustrated by Mr. Wallace's volume of Essays, "Contributions to the Theory of Natural Selection;" and it is mainly from the illustrations furnished in this work that I propose to derive my arguments as to its inadequacy. In the first place I wish to call attention to the fact which the Duke of Argyll has already acutely pointed out in his "Reign of Law," that the theory does not even attempt to explain the most inexplicable phenomenon in the development of these organic changes, namely, the first commencement of a tendency to variation. The title of Mr. Darwin's famous work, the text-book of the theory, seems to me, indeed, altogether a misnomer: "The *Origin of Species* by means of Natural Selection." Mr. Darwin admits the existence of what he terms a "spontaneous" tendency to variation among the offspring from a common ancestor; this "spontaneous" tendency is the only natural law which can correctly be termed that of the *origin* of species; all that Mr. Darwin and his disciples attempt to explain is the survival and propagation of certain among the diverse forms thus resulting in preference to others. Throughout the whole of Mr. Wallace's volume he appears to have no consciousness that his theory does not go to the root of the matter. When once the tendency to change has set in, there can be no doubt that "Natural Selection," "The Survival of the Fittest," whatever you like to term the principle, is one among many causes which tend to the perpetuation of certain forms. When, however, Mr. Darwin asserts, "I am convinced that Natural Selection has been the main, but not exclusive, means of modification,"* I am by no means prepared to go with him to that extent. Some of Mr. Darwin's disciples go even further, and seem to consider it, in fact, as almost the only means.

There is no phenomenon in Natural History which is more thoroughly relied on by the advocates of Natural Selection as furnishing a decisive argument in favour of their theory, than the one which forms the subject of the longest of the essays in Mr. Wallace's volume, that of Mimicry or Mimetism. I propose, therefore, to occupy the greater part of this paper with an inquiry how far the facts which have been adduced support the conclusions first brought prominently forward by Mr. Bates in his "Naturalist on the Amazons," and more fully elaborated and illustrated by Mr. Wallace. There can be no doubt about the frequent occurrence of "protective resemblances" in the animal kingdom. Certain classes of animals enjoy, from various causes, exceptional immunity from the attacks of their natural enemies. In order to share in these immunities, it is found that other animals, belonging to an entirely different class or order, whilst retaining all the structural characters of their own class, so closely resemble in external features of colour and form particular species of the favoured races as to be readily mistaken for them. How do the advocates of the theory of Natural Selection attempt to account for this superficial resemblance? By the continuous preservation, through countless generations, of those particular individuals which spontaneously approach most nearly to the ultimate forms.

Now, there are two principles admitted or insisted on by every advocate of Darwinism, which it is necessary to bear very clearly in mind in the following argument. The first is, that, in a state of nature those differences which ultimately become specific or generic are brought about by exceedingly slow gradations. And it is obvious that it must be so. For if by chance any strongly abnormal form is produced, even should it survive to generate offspring, which is in itself doubtful, it must necessarily cross with other less abnormal individuals, and its descendants would thus have a tendency to revert towards the parental form. On this point Mr. Darwin himself says: "It may be doubted whether sudden and great deviations of structure, such as we occasionally see in our domestic productions, are ever permanently propagated in a state of nature." † And again, "Natural Selection always acts with extreme slowness." ‡ The other point which I wish to be borne in mind is, that no change can possibly take place by the process of Natural Selection which is not directly of advantage to the individual. On this point again all the supporters of the hypothesis are agreed. Mr. Darwin distinctly affirms that "only those variations which are in some way profitable, will be preserved or naturally selected;" § and Mr. Wallace even more emphatically speaks of "the principle which Mr. Darwin so earnestly impresses upon us, and which is, indeed, a necessary deduction from the theory of Natural Selection, namely, that none of the definite facts of organic nature, no special organ, *no characteristic form or marking*, no peculiarities of instinct or of habit, no relations between species or between groups of species—can exist, but which must now be or once have been *useful* to the individuals or the races which possess them." ||

We have, therefore, established at the outset these two data: that the passage from the ordinary to the mimetic form is effected by a number of exceedingly small steps, and

* Paper read before Section D of the British Association, at Liverpool, September 20th, 1870.

* "Origin of Species," 4th ed., p. 6. † Ibid, p. 47. ‡ Ibid, p. 121. § Ibid, p. 131

|| "Contributions to the Theory of Natural Selection," p. 47.

that every one of these changes must present some advantage to the species which undergoes it. Now let us apply these two principles to the recognised facts of Mimetism; and for this purpose we may take a single instance, one of the most remarkable and best authenticated, recorded by Mr. Bates in his "Naturalist on the Amazons," and more fully in his paper on the "Lepidoptera of the Amazon Valley," in the "Transactions of the Linnean Society." There is in South America a tribe of butterflies of very gaudy colour, the *Heliconidæ*, which appear to enjoy exceptional immunity from the attacks of birds, from the exudation, when attacked, of a nauseous fluid, and are consequently extremely abundant. Another South American genus of Lepidoptera, the *Leptalis*, belongs structurally to an entirely different class, the *Pieridæ*, and the majority of its species differ correspondingly from the *Heliconidæ*, in their size, shape, colour, and manner of flying, being nearly pure white, and of the same family as our common cabbage butterfly. There is, however, one particular species of *Leptalis*, which departs widely in external facies from all its allies, and so closely resembles a species of *Ithomia* belonging to the *Heliconidæ*, as apparently not only to deceive the most experienced entomologists, but even to take in its natural enemies also, and, although perfectly harmless, to share the immunity of the butterfly it simulates. Mr. Bates and Mr. Wallace have both attempted to show, with great ingenuity and plausibility, that this entire change from the normal form to that resembling the *Ithomia* has taken place through the agency of natural selection acting through a long series of generations. I believe, however, on careful examination, the line of argument will be found to break down, and that at its very outset, on the ground that the early stages of the transformation will be perfectly useless for the protection of the species.

Applying the rigid test of mathematical calculation to the problem, I think it may safely be assumed that it would require, at the very lowest calculation, one thousand steps to enable the normal *Leptalis* to pass into its protective form. Mr. Bates indeed assumes that the change may have taken place much more rapidly, but this appears a very unsafe and unsupported deviation from the sounder principle laid down by Darwin and Wallace. It is indeed obvious that any marked variety resulting suddenly must inevitably revert, as already observed, more and more towards the parent type by crossing, unless, indeed, we are to suppose that a pair, male and female, are simultaneously produced with a deviation in exactly the same direction, and that their offspring keeps itself apart, interbreeding only with itself as a separate colony,—an assumption contrary to all experience. At all events, we may safely say that within the historic period no such change has been effected within a vastly larger number of generations, where human agency has not come into play. The next step in my argument is, that the smallest change in the direction of the *Ithomia*, which we can conceive on any hypothesis to be beneficial to the *Leptalis*, is at the very lowest one-fiftieth of the change required to produce perfect resemblance. I believe myself that a very much larger fraction, say one-fourth or one-third, would be practically useless; as I am told by practical entomologists that birds will distinguish with accuracy caterpillars suited for their food from other species scarcely distinguishable to our eyes, which are not so suitable. For the sake of argument, however, I will suppose that a change to the extent of one-fiftieth is beneficial to that small extent *after which* natural selection may begin to come into play. Mr. Wallace, indeed, argues that an infinitesimal and inappreciable distinction may make the difference of a slightly longer span of life being allowed to the butterfly, to lay its eggs in safety; but this is a deductive piece of reasoning derived from the theory, because necessary to it, and not inductive observation from nature; and I altogether decline to be carried further, for the sake of the theory, than the limit I have indicated. Suppose a parallel instance: that our common brown owl has a *penchant* for mice, while moles are abhorrent to its palate; is it conceivable that, supposing a mouse was born approaching a mole by the one-hundredth part in external appearance, say with feet a fraction of a line broader, or eyes slightly deeper set, the shortest-sighted of owls would for a moment mistake *Mus* for *Talpa*? Or, a still more parallel instance: suppose a blue-bottle fly were born blessed with a slightly narrower waist, or a faint band of yellow on its body, will any one maintain that it stands the least chance of escape from destruction by those birds which do not feed on wasps? And no one who has examined Mr. Bates's or Mr. Trimen's beautiful drawings, or, still better, the insects themselves, will say that I have exaggerrated the extent of the passage from the normal to the imitative *Leptalis*.

If, therefore, this reasoning is sound, one thousand steps being necessary to effect this change in external appearance, and one-fiftieth of the whole change, or twenty steps, being the smallest amount that is really profitable to the animal, it follows that the first twenty steps of the transformation are not due to natural selection, but must have taken place by an accumulation of chances. Let us investigate the value of this chance. Suppose there are twenty different ways in which a *Leptalis* may vary, one only of these being in the direction ultimately required, the chance of any individual producing a descendant which will take its place in the succeeding generation varying in the required direction, is $\frac{1}{20}$; the chance of this operation being repeated in the same direction in the second generation is $\frac{1}{20^2}$ or $\frac{1}{400}$; the chance of this occurring for *ten* successive generations (instead of twenty, as I have assumed above) is $\frac{1}{20^{10}}$, or about one in ten billions. Now another factor comes into the calculation, and that is the number of individuals among which this chance is distributed. Mr. Bates and Mr. Wallace agree in stating that both in South America and in the Malay Archipelago the imitative species are always confined to a limited area, and are always very scarce compared with the imitated species. We will assume that the number of individuals of the imitative *Leptalis* existing at any one time is one million; the chance of there being among these million a single individual approaching the *Ithomia* to the extent of one-hundredth is $\frac{1000000}{10000000000000}$, or the chance against it is ten million to one.

It will be seen that in the above calculation I have endeavoured to throw every advantage into the scale of the natural selectionist. I believe myself, and I think most naturalists will agree with me, that vastly more than a thousand generations, each characterised by a small change, must be conceded; and that, on the other hand, a change to the extent of even greatly more than one-fiftieth would be absolutely useless. This idea receives great confirmation from observing the most wonderful identity of the marking in the mimicked and mimicker. If a rough imitation is so useful, it must be a mere freak of Nature to produce so absolute an identity, and we are landed in the dilemma that the *last* stages are comparatively useless. If, again, I had carried on the calculation to $\frac{1}{20^{20}}$ instead of $\frac{1}{20^{10}}$, it would have been difficult to have stated the result in figures; and if, on the other hand, it is objected that a million is too low an estimate of the number of individuals existing at one time, and a hundred million or a thousand million is substituted (an altogether inconceivable estimate for a rare conspicuous butterfly limited to a small area *), the result will not be materially affected. For, supposing the chance is reduced from one in ten million to one in ten thousand—and it is said that the world has existed quite long enough to give a fair chance of this having occurred once—it is not a solitary instance that we have. Mr. Bates states that, in a comparatively small area, several distinct instances of such perfect mimicry occur; Mr. Wallace has a store in the Malay Archipelago; Mr. Trimen records several of wonderful beauty and exactness in South Africa; and the more attention is turned to the subject, the more numerous do instances of mimicry become.

I have left out of account altogether those still more remarkable instances, which are even more difficult to explain on the theory of natural selection (as the number of steps must be infinitely greater), in which animals not only imitate others belonging to entirely different natural orders, as Diptera mimicking Hymenoptera, and caterpillars snakes, but where they resemble inanimate objects. The weird and uncanny resemblance of the *Phasmata* and *Mantides* to dry leaves and sticks has long been known: not only is the veining of the leaves accurately reproduced, but the attacks of parasitic fungi are simulated; and Mr. Wallace records instances of larvæ bearing the most minute resemblance to the droppings of birds, and spiders to the axillary buds of plants. Through what countless generations must these transformations have been effected! and by what mathematical formula could we express the chance against their occurrence, if

* The latter number would give 150 individuals per acre over an area 100 miles square, or 50 per acre for an area as large as Ireland.

natural selection only had been at work in their production? The difficulties in the way of the natural selection explanation are also materially increased when we find, as is often the case, that it is one sex only (the female) which undergoes these mimetic changes, and that the changes have to take place simultaneously in the direction of colour, size, form, and habit.

It may now fairly be asked, if the principle of natural selection is abandoned as the main cause of these wonderful modifications, what other theory can be substituted in its place? I do not know that the objector to a theory is always bound to provide another theory as a substitute. Mr. Darwin, in his "Variation of Animals and Plants under Domestication," quotes with well-deserved approval Whewell's aphorism, that "Hypotheses may often be of service to science, when they involve a certain portion of incompleteness, and even of error." Mr. Darwin's and Mr. Wallace's hypothesis of natural selection has been of signal service to science; but if this hypothesis has been too rashly handled and too widely applied, it may be equally serviceable to point out its incompleteness or its error, as the first step to a still more scientific explanation. In the following remarks, I merely wish to call the attention of naturalists to one or two points which I think have almost been lost sight of in the discussion.

I have already adverted to the inaccuracy of the title of Mr. Darwin's great work, "The *Origin of Species* by means of Natural Selection." The opponents of Darwinism, even so acute a reasoner as the Duke of Argyll, appear to see no alternative between the theory that species have arisen through the agency of external causes, and the theory that species have remained immutable since their creation. I can accept no such alternative. Indeed we may say that external influences *cannot* be the primary cause of the transmutation of species. The utmost claimed by the theory of natural selection is, that it selects the fittest from already existing so-called "spontaneous" varieties. Every page of Mr. Darwin's work teems with reference to this pre-existing tendency to variation, with respect to which he says: "Our ignorance of the laws of variation is profound." Mr. Bates, when speaking on the subject of mimicry, makes the following very remarkable admission:—"It would seem as though our *Leptalis naturally produced* simple varieties of a nature to resemble *Ithomiæ*."* By a careful study of the context, I can only conclude that Mr. Bates means the same thing by his "natural" varieties as Mr. Darwin does by his "spontaneous" variations, namely, an innate tendency to vary *not caused by natural selection*, but on which tendency natural selection operates, and without which it would be perfectly inoperative. The use of the term "spontaneous" is open to objection from a philosophical point of view. It either means that the phenomena in question are subject to no law, or that they are the result of some law with which we are unacquainted. The former hypothesis will probably be rejected by every scientific naturalist, and must be utterly abhorrent to the believer in a "Reign of Law." This tendency to variation in the offspring meets us on every side in our investigation of nature. Every gardener knows how uncertain is the produce of seeds compared with the produce of buds or offshoots from the same plant. The ordinary mode of obtaining new varieties of strawberries or other fruits is from seeds. An endless variety of the commonest florist's flowers is produced by sowing seeds from the same capsule. Of the laws of this variation we are, as Mr. Darwin says, "profoundly ignorant;" but it does not follow that a patient interrogation of nature pursued in the true Darwinian spirit, may not reveal to us something of these laws. Of one thing we are certain, that natural selection here plays no part. If then we must admit that the first beginning of change takes place without the operation of this principle, why should we claim for it the main, almost the exclusive agency, in the changes which follow? Some other principle, at present unknown to us, originates these variations; what right have we to say that this principle, whatever it may be, then ceases to act, instead of being the main agent in all the other subsequent changes?

But are we limited to negative evidence in tracing the transmutations of species mainly to some unknown internal law? A single sentence in Mr. Wallace's Chapter on Mimicry seems to me pregnant with results for the future inquirer. He incidentally remarks how frequently it is the case that, when mimicry has once set in by the action of natural selection, new habits and instincts come into play to assist in the mimicry. It does not, however, appear to occur to Mr. Wallace to trace any connection between the instinct and the mimicry. The connection will be found, I believe, to be very close. Passing by for the moment any definition of instinct, let us trace its range in the organised world. From the whole vegetable kingdom it is conspicuous by its absence. In the lowest classes of the animal kingdom, the Protozoa and Cœlenterata, it is found, if at all, in a very low form; and though there is a popular superstition that oysters may be crossed in love, yet we cannot attribute to the Mollusca as a class any strong development of the instinctive faculty. When, however, we come to the Articulata, and especially to the Insecta and closely allied Arachnida, we meet at once with developments of instinct rivalling, if not exceeding in perfectness, those found in the highest forms of animal life. In the lower orders of Vertebrata again, the Pisces and Reptilia, we apparently come to a retrogression in the instinctive faculty, which is once more strongly developed in the Aves and Mammalia. Now let us compare this with what is known of Mimicry. From the vegetable kingdom it is absent. There are, it is true, resemblances, and resemblances of the most wonderful and perfect kind, in the marking and venation of the leaves of plant belonging to entirely different natural orders, equal in extraordinary closeness to those of which I have spoken in the animal kingdom; but these are in no sense mimetic or protective. Mere protective resemblances of colour I consider of far less importance than of form or habit; since colour may unquestionably be affected directly by the external circumstances of light, &c., and varies "spontaneously" in both the animal and vegetable kingdom to a far greater extent than does form. In the lowest forms of animal life we have no well-authenticated instances of mimetism, the most striking among the Mollusca with which I am acquainted is one pointed out to me by Mr. G. S. Brady in the beautiful *Lima hians*.* But when we come to insects, we find protective resemblances of the most extraordinary kind, in marking, in form, in habit, presented to us on every side. Among fishes and reptiles the principle appears to be again comparatively in abeyance, and to be once more strongly developed in birds. The parallelism is indeed almost complete. In short, the power of mimetism, as far as is known at present, runs almost *pari passu* with the development of the nervous system.

But what is instinct? Modern naturalists are pretty well agreed in abandoning the old distinction in kind between reason and instinct, and in considering the nest-building instinct of birds and the cell-constructing instinct of bees, as but a lower form of the same faculty which we call reason in ourselves. It is admitted that this instinct teaches the bee which flowers to rifle for its honey, and even to modify its habits in accordance with the circumstances in which it is placed; but, according to the prevalent theory, it has no power to modify its proboscis so as to enable it to obtain the honey from the flower, or to modify its wings to suit to its new habit. In short its own body is almost the only thing over which the animal has no power. To me such a restriction appears to be unphilosophical. I cannot but believe in the existence of an unconscious Organising Intelligence, an idea which Mr. J. J. Murphy has ably and logically advocated in his "Habit and Intelligence." And if this inherent innate power of change is admitted, it at once harmonises the tendency to variation which exists in all created beings, with the perpetuation of those forms best adapted to resist the struggle of life, and lends to natural selection the assistance of a fellow-worker far more powerful and of more universal operation.

A powerful argument in favour of this view may be drawn from Mr. Wallace's volume. Every reader of that book must have been struck with the remarkable manner in which he completely abandons and casts aside his own theory when he comes to treat of man. Natural selection is amply sufficient to account for all the other transmutations in the animal kingdom; only give time enough, and it is competent to develop the elephant out of the *Amœba*—the one step in the animal creation which is beyond its power is that from the ape to man; all the infinite forms of the brute creation have resulted from this principle,—to produce the different races of mankind some other power is needed. In a singularly able review of this work in the *Archives des Sciences Physiques et Naturelles*, M. Claparède, of Geneva, points out with great acumen the singular inconsistency of this reasoning; and shows how great a want of faith in his own principle it betrays on the part of its author. Mr. Wallace's line of argument is very interesting. We may take only a single instance. Man is the only terrestrial mammal with a bare hairless back. All savage nations feel the want of a covering to their back; in cold countries to protect them from the cold, in

* Transactions of the Linnean Society, vol. xxiii., p. 512.

* See NATURE, Vol. ii., p. 376.

hot countries to protect them from the heat of the sun. It is impossible to conceive, therefore, that this absence of covering was ever directly beneficial to the race or the individual; and hence it cannot have been produced by the operation of natural selection; but must have been in some way connected with those reasoning powers which lead to the construction of clothing and dwellings on which his civilisation so largely depends. Mr. Wallace, however, appears to forget that he had previously stated his conclusion that "those great modifications of structure and of external form which resulted in the development of man out of some lower type of animal, must have occurred *before* his intellect had raised him above the condition of the brutes."* This principle, therefore, whatever it may be, other than natural selection, which produced man's bare back, must have been in operation before the intellect of man was developed. This strange inconsistency of Mr. Wallace's appears to result from the fact that he is unable to shut his eyes to the inevitable conclusion that the development of man from the ape, and the production of the different races of mankind, have not resulted from the operation of natural selection, pure and simple, but that this principle has been powerfully assisted by man's reasoning faculties. This reasoning seems to me perfectly sound and inevitable, admitting, for the sake of argument, Mr. Wallace's hypothesis, that man *is* descended from the apes; but, if we consistently believe in the action of general laws which govern the whole of animated nature, we must carry the argument back a step further. Reason is but a higher development of instinct. If man's reason has assisted him so to modify his body as to adapt himself to the circumstances with which he is surrounded, we are unable to bring forward any valid argument why the instinct of animals should not also assist them to modify their bodies, by slow and gradual degrees, so as to adapt them to the circumstances with which they are surrounded.

In the essay alluded to above, M. Claparède, himself one of the few genuine Darwinians among French writers, points out the dangerous and unscientific manner in which the theory of natural selection is made, in the hands of its too zealous advocates, to explain phenomena which are probably due to other causes. The discovery of this law marked an era in the history of natural science, and gave a wonderful impulse to original research. The danger now is that the law will be pressed into services which have no claim upon it; and that, in the hands of injudicious partisans, it will become a hindrance rather than an aid to science, by closing the door against further investigations into other laws which lie behind it. To claim for Natural Selection the main agency in the creation of the countless forms of organic life with which we are surrounded, is straining it beyond its strength. An era of equal importance will be marked by the discovery of the law which regulates the tendency to variation which must necessarily underlie natural selection.

The argument of "design" was undoubtedly pushed by pre-Darwinian writers to too great an extent. The most recent phase of Darwinianism, however, is a complete denial of the existence of design in Nature. It is the carrying into Natural Science of the Hobbesian principle of Self-love. Every individual and every species exists for its own advantage only, and has no *raison d'être* except its own welfare. To my mind the beauties and wonders of Nature seem, on the other hand, to teach a different lesson, that,

> All are but parts of one stupendous whole,
> Whose body Nature is, and God the soul;

that there are laws, albeit almost unknown to us—not laws merely of external circumstance, but laws of internal growth and structure,—which actively modify each individual organism, not only for its own advantage in the struggle for life, but for the higher end of subordinating every individual existence to the good of the whole.

THE PROFESSORSHIP OF NATURAL HISTORY, QUEEN'S COLLEGE, BELFAST

IN a late number we announced that Professor Wyville Thomson, of the Queen's College, Belfast, had been appointed by the Crown to the Professorship of Natural History in the University of Edinburgh. This will necessitate the resignation by Professor Thomson of his chair in the Queen's College, Belfast, a resignation which we may presume will be made before the commencement of the next term, and a resignation in which some of our readers and many of our men of science will take an interest, for the places of honour or emolument open to the student of Natural Science in this country are so very few, that there is naturally much excitement when one of the few is to be filled up. Already we hear of a whole host of young and meritorious workers setting their faces towards the city that boasts to be the Athens of the North of Ireland. The mere mention of the names of Dr. Cunningham, who in the Straits of Magellan earned his Natural Science spurs so well, of Mr. E. Ray Lankester, whose numerous papers show an intimate acquaintance with zoology, of Dr. Macalister, whose comparative anatomy memoirs are so well-known, or of Dr. Traquair, whose papers on fossil fish and on the skull of recent Pleuronectidæ are of high merit, not to name others, will show that the post of Professor of Natural History in the Queen's College, Belfast, will be contested for by a little army of well-educated and accomplished gentlemen, the selection of any one of whom would reflect credit on the College.

But a rumour reaches us that there may be no election to the Professorship after all—that the spirit of economy is to annihilate the spirit of competition; that, in order that the Government of this great country may save certain paltry trifling possibilities of pension, it is their intention to translate to Belfast one of the four Professors of Natural Science in the Queen's Colleges of Cork and Galway. It is necessary to explain how this can be done. Each of the Queen's Colleges had originally a Professor of Geology and Mineralogy, and a Professor of Zoology and Botany. Their income was that of a junior assistant in the British Museum, and for common decency's sake, it was found necessary to raise it; this was done on the condition that each of the Professors undertook to lecture on the subjects at the time lectured on by his colleague, on the death or resignation of that colleague, without further increase of pay. So when Prof. Dickie, who was Professor of Botany and Zoology in the Queen's College, Belfast, resigned, on his removal to Aberdeen, Prof. Thomson had to lecture in zoology and botany, in addition to his own subjects of geology and mineralogy. Thus it happens that should the Government confer the vacant Belfast chair on one of the four existing Professors of Natural Science in the other two Queen's Colleges, his post in the college which he leaves will be filled up by his colleague, and the Crown will have to deal in the matter of pension, &c., with but four persons instead of with five, as they will have if they appoint a candidate who is not one of these four Professors to the vacant post. Nor can the Crown confer this Professorship on one of the present Professors, and then fill up the place thus left vacant by a new appointment, because, although the yearly salary of the colleague of the Professor thus elected will not be increased thereby, yet his fees, to a slight extent, will; and so, to break the bargain made, would be to the detriment of the individual—a thing, we believe, no Government would do. But why, we ask, should they, for a paltry saving, do detriment to the cause of Science in this country—courted when she is needed—kept at more than arm's length when it is imagined she may be done without? Science is but badly cared for in our country, and we here allude to the above facts for the purpose of urging those to whose care this appointment falls, to forget, for the once, all considerations except those for the good of the College, and to quicken the already expanding life of the Queen's University in Ireland by the infusion of fresh blood into this one of its Colleges.

It is in the interest of Science that we write, not in the interest of candidates, one of whose names we would not mention above another.

X

PITCHER PLANTS

DIFFERENCE of opinion has been expressed as to the nature and use of the liquid found in the so-called pitchers of various plants, such as Nepenthes, Rafflesia, and certain Orchidaceæ. The popular idea that these curious receptacles collect pure water for the refreshment of the thirsty in arid places, would seem to be set at rest, by a consideration of the fact that these plants grow in moist and marshy places. There would seem, moreover, to be some improbability that plants should secrete pure water.

In this country, where these plants are grown under exceptional conditions, there is some difficulty in settling these questions experimentally. In such cases, extraneous water often finds its way into the pitchers, so that several ounces may frequently be gathered from a single receptacle of Nepenthes, the greater part of which is accidental.

In August last I had an opportunity of collecting the liquid from two flowers of Coryanthes, one of the Orchidaceæ, which had just opened, in one of the well-known stove-houses of Mr. Wilson Saunders.

Though the quantity collected was small, amounting only to about three cubic centimetres, or 1·18 cubic inches, an examination showed the following properties :—

Clear and somewhat glutinous in consistence. Possessed of a high refractive power, and a specific gravity of 1·062.

Odour pleasant but faint, becoming more marked by a gentle heat. Neutral to test papers. Becoming milky, by concentration on the water-bath, it finally yielded a transparent gum, insoluble in alcohol.

Oxalates produced no precipitate of lime, but basic lead acetate gave a curdy reaction. Concentrated hot sulphuric acid blackened the liquid.

Although the taste was not acrid, the mawkish flavour would render it quite unpotable.

This examination therefore proved the liquid to be something else than pure water.

100 parts of liquid contained :—

Water and volatile oils . .	98·51
Non-volatile residue. . . .	1·49
	100·00

G. B. BUCKTON

SPECTROSCOPIC OBSERVATIONS OF THE SUN

PROF. C. A. YOUNG has obligingly sent me an account of his recent work, which is very rich in promise, as he tells me that he has now the dispersive power of 13 prisms of heavy flint, each with an angle of 55°. It is now some time ago since I announced to the Royal Society that over spots prominences, built up of different vapours, were sometimes observable by means of their lines, *bright and thin*, overlying the thick absorption lines in the spot spectra. This observation is, I hold, a clear proof of the truth of the theory put forward by Dr. Frankland and myself, namely, that changes in spectra, notably the thickening of the lines, are due to pressure, and not to temperature; for according to the theory of exchanges, the bright prominence must be hotter than the absorbing vapour which underlies it, and still the lines are thinner.

Dr. Young has now observed these phenomena with exactly the same result. He writes to Professor Morton :—

"I write to inform you that last Thursday, Sept. 22, about 11 A.M. Hanover mean time, I was so fortunate as to see the sodium lines D_1 and D_2, reversed in the spectrum of the umbra of a large spot near the eastern limb of the sun. At the same time the C and F lines were also reversed, but with the great dispersive power of my new spectroscope I see this so often in the solar spots, that it has ceased to be remarkable.

"The figure gives the appearance of the sodium lines. In the umbra of the spot the D_3 line was not visible, but in the penumbra was plainly seen, as a dark shade, represented in the figure.

"I am not aware that this reversal of the sodium lines in a spot spectrum has ever been observed before; its reversal in the spectra of prominences is not very unusual. A small prominence on the western limb of the sun, which was visible the same forenoon, presented all the following bright lines, viz. : C, D_1, D_2, D_3, 1474°, b_1, b_2, b_4, 1989·5, 2001·5, 2031°, F, 2581·5, 2796°, and h; 15 in all.

"In the spot spectrum the magnesium lines b_1, b_2, and b_4 were not reversed, but while the shade which accompanies the lines was perceptibly widened, the central black line itself was thinned and lightened."

Further, Prof. Young has succeeded in obtaining photographs of protuberances on the sun's limb, of which he has been good enough to forward me a specimen. They were obtained by attaching a small camera to the eye-piece of the telescope and opening the slit somewhat widely, using the hydrogen line near G. He adds :—"As a picture, the little thing amounts to nothing, because the unsteadiness of the air and the maladjustment of the polar axis of the equatorial caused the image to shift its place slightly during the long exposure of three-and-a-half minutes which was required, thus destroying all the details. Still, the double-headed form of the prominence is evident, and the possibility of taking such photographs is established."

In a letter to myself Prof. Young adds :—"I should not have published so imperfect a success were it not that my engagement as a member of Prof. Winlock's eclipse party prevents me from following up the matter at present. The experiments were tried on the 28th, and on the 30th the equatorial was taken down to be packed up and sent to the rendezvous, at Alvan Clark's factory, where all the instruments are collected and put in order previous to sailing."

J. NORMAN LOCKYER

NOTES

SINCE our last issue the Joint Committee of the Royal and Royal Astronomical Societies and the Council of the British Association have met to consider the question of the Eclipse Expedition, and in consequence of these meetings Mr. Gladstone has been asked to receive a joint deputation to urge upon the Government the importance of the proposed expedition. The Joint Committee have appointed the Presidents of the Royal and Royal Astronomical Societies, the Astronomer Royal, and Mr. Lockyer to plead its cause; while the Council of the British Association will be represented by the President and officers of the Association, Sir John Lubbock, M.P., and Dr. Lyon Playfair, M.P. Up to the time of our going to press, however, no time had been fixed for the deputation to wait upon the Prime Minister.

THE medals in the gift of the Royal Society have this year been awarded as follows :—The Copley medal to Dr. Joule; the Rumford medal to M. Descloiseaux; and the Royal medals to Prof. W. H. Miller and Mr. W. Davidson.

PROF. SIMON NEWCOMB has arrived in this country from the United States Naval Observatory. His mission among us is to examine and report on the great Newall telescope. He will then proceed to Gibraltar to observe the approaching eclipse.

ALL members of the British Association will be concerned to learn that Dr. Hirst feels called upon by the pressure of his new duties to resign the General Secretaryship of the Association, an honorary post which he has long filled with the greatest advantage to Science.

AMONG the mass of correspondence which has recently reached us are several interesting letters on early notices of the Aurora, for some of which we hope to find room next week.

WE rejoice to see several men of science, with Professor Huxley at their head, coming forward as candidates for the London School Board. We shall be glad to be informed if this example is followed elsewhere.

WE read in the *Echo* that the Electric Telegraph has been put to a new use in Canada. At Mimouski, when the late earthquake came upon them, they sent at once to Quebec, a distance of 200 miles, to ask, "How do you feel?" While the operator there was at his work the shock arrived. He at once sent to Montreal, about 200 miles further on, to ask if they had felt it. They had just time to say "No" before the earthquake came up.

THE new buildings of the Glasgow University were formally opened on Monday last. The proceedings were conducted within the Hunterian Museum. The Duke of Montrose, Chancellor of the University, presided, and congratulated the principal professors upon the success which had attended their efforts, and that they had lived to see the opening day of the new University. The merchants of Glasgow had made princely fortunes, which was creditable to their talents and their industry; but it was still more creditable to them that they had made such a use of their riches as to enable this noble building to be erected for the education of the rising generation. After Prof. Lushington had delivered an address, Mr. A. Orr Ewing, M.P., stated that from subscriptions and from Government 254,000*l.* had been obtained, and 117,000*l.* had been received for the ground upon which the old college stood. Everything in connection with the new building was paid. Of the 150,000*l.* in public subscriptions, Glasgow had given nearly all. The various classes met on Tuesday.

WE believe that Mr. W. Spottiswoode will succeed the late Dr. W. A. Miller as Treasurer of the Royal Society.

ON the 15th inst., Dr. Grey will read a paper at the Statistical Society "On the Claims of Science to Public Recognition and Support." We are glad that the attention of such a powerful body as the Statistical Society is to be so authoritatively drawn to such an important subject.

THE Polytechnic School of Zürich has been suddenly deprived of its chemical teachers. In addition to the death of Prof. Bolley, which we have already recorded, Prof. Hädeler, giving way to the demands of failing health, has relinquished his chair of Pure Chemistry.

IT was recently determined to erect a statue to Prof. Morse, the eminent American electrician and inventor of the telegraph which bears his name, and for this purpose subscriptions were opened in the States. The full amount has been very speedily subscribed, and the erection of a marble statue is to be at once proceeded with. It is to stand in the Central Park, New York, a suitable position having been willingly granted by the Commissioners.

IT is a question of some interest and curiosity how to compare the forces of steam and gunpowder. The following calculation, each step of which can be easily followed, may therefore be acceptable to our readers. The force exerted by an exploding charge of powder in a gun requires for its calculation two considerations, *viz.* the amount of force given to the shot, and the time in which that force is imparted. Taking as our example the 300-pounder Woolwich gun, the first element of the calculation is as follows:—One steam horse lifts 33,000lb. one foot in one minute, or 550lb. in one second. The 300lb. shot leaves the muzzle of the gun at the rate of 1,300 feet per second. Let H represent the force in horse-power in the shot, then, by the well-known equations $W = \frac{1}{2} m v^2$, and $m = \frac{w}{g}$,

$$H \times 550 = \frac{300}{2g} \times (1{,}300)^2 = \frac{300}{64} \times 1{,}690{,}000,\ H = 14{,}403{\cdot}409$$

The force, *i.e.* the work in the shot, is therefore measured by 14,403·409 horse power. That is, it would require that amount of horse power acting for the space of one second to give to a 300lb. shot the velocity with which it is driven from the gun by the explosion of the charge (43lb. of gunpowder). But this is done by the powder during that minute portion of a second in which the shot moves down the bore of the gun. The results of Captain Noble's chronoscope make it appear that this time is somewhat less than one two-hundredth part of a second. The force exerted by the powder must, therefore, be 14,403·409 × 200: that is 2,880,681·8 horse power. Some comparatively small considerations, as the friction of the shot in the gun, are neglected in this calculation. It does not, therefore, err in excess, and is sufficient to give some idea of the enormous force exerted. Nor is it uniformly exerted throughout the whole time of the shot's movement in the gun, nor does the calculation above made necessarily give the greatest intensity of action. This much we may state, that at some *instant* during the 200th part of a second in the case taken, the force of the expanding gas was to be measured by nearly three million horse power.

THE unpublished manuscripts left by the late Sir James Simpson on the important subject of Hospitalism have been confided to the care of Mr. Lawson Tait, of Birmingham, for completion and editing.

IN addition to the outbreak of the long-quiescent volcano of Tongariro in New Zealand, to which we lately called attention, we hear from American sources that "a volcano, near San Rafael Valley, Lower California, which has been in a dormant state for years, has commenced a violent eruption, emitting columns of smoke and scattering ashes and cinders for miles around its base. St. Diego telegrams say it is plainly visible from there."

THE islands in the Sea of Okotsch, off the north-east coast of Asia, are being visited by ships in search of seals. A vessel recently arrived at San Francisco from Jones Island, between lat. 52° and 53° and long. 145° and 146°, with 11,500 seal-skins on board, and another vessel with a still larger cargo is expected. This island is half a mile in circumference, and is uninhabited, and is remarkable for the great abundance of seals.

CONSIDERING the many uses to which india-rubber is now applied, one of the most important being its recognised superiority over gutta-percha for deep-sea telegraphs, and remembering the fears entertained some time back of the probability of a decrease in the supply, owing to the exhaustion of the forests consequent upon the immense demand, it is gratifying to learn that the quantity of rubber exported from Para during the past year exceeded that of the previous year by 22,731 arrobas (an arroba is equal to about 25¼lb.), and by 241,250*l.* in market value. It is true that the more accessible rubber districts are becoming exhausted, and give a smaller yield than in former years, but the rubber-bearing country is so extensive, and its rivers so incompletely explored, that the newly-discovered sources will, no doubt, more than make up any deficiency arising from the exhaustion of the old. It is difficult, however, to obtain accurate or reliable information from those engaged in the collecting of the rubber. The continued demand for rubber, which is collected with comparatively little labour, and requires but little skill and experience, absorbs all the attention of the natives over other products, and the constant rise in its value so stimulates its production, that it is more than probable there will be for some years to come an annual increase in the quantity imported of at least ten per cent.

In the State of Santander, Colombia, one of the most important sources of state revenue is the manufacture of so-called straw hats. These hats are chiefly made in the Bucaramanga district, and are of a very fine and white material, but still not equal to the celebrated Panama hats, as they soon become dirty, owing to the plait not being drawn sufficiently tight. The weekly sale of hats in the above district averages from 600 to 800 dozen, the lowest quality of which fetch about 1*l.* 4*s.* the dozen, and the finest quality often realising as much as 1*l.* 10*s.* to 1*l.* 16*s.* each. These latter are principally made near Zapatoca, which also has a large trade, but not to the same extent as Bucaramanga. They are for the most part exported to Havana and the United States, where there used to be a great demand for them, but now the trade seems to have somewhat diminished. In the first half of last year 250 cargoes were exported, and as each cargo contains 1,200 hats, some idea may be formed of the large quantities manufactured. The above is gathered from a report on the industrial resources of the State of Santander. The hats referred to are described as being made of a white kind of "straw." We have not seen any of the actual material, but think, in all probability, the so-called straw may be the split leaves of some palm, perhaps *Thrinax argentea*, which was imported in considerable quantities some years ago, and manufactured at St. Alban's into "chip" hats.

The astronomical and meteorological observations made at the United States' Naval Observatory during 1867 have just been published in a large quarto volume. There is an appendix of reports on the observations of the total eclipse of the sun of Aug. 7, 1869, the various phases of which are beautifully illustrated by chromo-lithographs, and the various instruments made use of are particularly described.

A piece of meteoric iron fell on the 18th of September last near Santa Clara, California, in the barn-yard of Michael Sanor, where it set the straw and *débris* on fire. When picked up it was exceedingly hot, and hissed when thrown into water. The meteorite which fell in October 1869 in Stewart County, Georgia, will be analysed, and a full description of its fall and accompanying phenomena given in the next number of *Silliman's Journal*, by Prof. Willet.

In consequence of the depression caused by the war, the private enterprise for working coal near Manita in Asia Minor has been postponed, but the Government is taking measures at length for working the coal formations near Constantinople for the artillery factories, carried on under the direction of Messrs. Siemens. This coal was known and worked seventy years ago, as described in old books of travels, and then abandoned. The Heraklea coal mines are going on slowly.

The Government of India is now cooling in its reduction fit, consequent on the supposed deficiency in the Budget, and is paying more attention to the discharge of its duties. The appointment of an assistant curator for the Geological Museum of India has been authorised, and an increase allowed for the literary purposes of the department.

It is reported from that interesting region, the Argentine States, that two enormous fossil skeletons have lately been discovered at Fray Bentos, but they are so large as to be beyond the local means of transporting them with safety.

A great earthquake has taken place in the town of Santo Tomas, the capital, and in the district, of Chumbivilcas, department of Cuzco, Peru. On the 10th of July, about 1.30 P.M., it was felt as the people were coming out from mass. The upper part of the two side towers of the church fell in, the vaulted roof was rent, as well as the walls, and much more damage done. Other damage also took place in the town and district. On that same day the River Santo Tomas, which runs about a league to the west of the town, suddenly rose and overflowed its banks, producing great destruction to the farms, horses, and cattle, but no lives were lost. It was afterwards ascertained that by force of the shock the waters of the Lake Quenacocha had broken out into the river. The lake is about 20 miles in circumference, and lies at the base of the western chain of the Andes. In the town of Ccolqquemarca, the tower and body of the church were injured, and many houses overthrown. Up to the 12th the earthquakes were felt every few minutes, at least every quarter of an hour, and the river was still flooded. On the 13th August there was a slight earthquake in the evening at Lima. On the 27th August an earthquake was felt in Chile—we presume at Valparaiso.

Efforts are being made to obtain improved instruments and to extend the observations at the Meteorological Observatory at Durban, in Natal.

In continuation of our comments on the caution necessary in dealing with scientific statements in the Indian press, we may advert to a case in which the Welsh fasting-girl is eclipsed. A correspondent of the *Indian Daily News* at Nuddea affirms that a Sudra woman, forty-five years old, has abstained from food twenty-five years. She bathes twice a day. Of course it is to be added that many natives have satisfied themselves of the correctness of this statement, as many Welshmen did with regard to their fasting-girl.

The *Inverness Courier* of October 13 states that a number of hollow glass globes of a dark colour, and measuring about eighteen inches in circumference, have lately been found washed ashore at various parts of the coast on the west side of the Island of Lewis. They are hermetically sealed, and have certain characters, such as IV or VI impressed on the sealed part. Some of them are partially filled with a colourless liquid. The question is asked: "Have these been used for some experiment made for the purpose of ascertaining the course of some ocean current?" Can any of our readers throw light on this subject?

In a recent number of the *Pharmaceutical Journal* a paper appears, by Mr. Cooke, on the Guarana, the seeds of a tree termed the *Paulina sorbilis*, belonging to the order *Sapindaceæ*, and abundant in the province of the Amazonas. The fruit is scarcely as large as a walnut, and contains five or six seeds, which are roasted, then mixed with water and moulded into a cylindrical form resembling a large sausage, and finally dried in an oven. Before being used it is grated into a powder, very like powdered cacao in appearance. Two spoonfuls of the powder are mixed in a tumbler of water, and this drink is regarded as a stimulant to the nerves, and like strong tea or coffee is said to take away the disposition to sleep. The active chemical principle is an alkaloid which Dr. Stenhouse has shown to be identical with theine. Guarana contains more than double as much of this alkaloid as good black tea, and five times as much as coffee, the proportion being 5·07 per cent in Guarana. It is rather a singular coincidence that the same alkaloid should prevail in all the principal substances employed in a similar manner as beverages in different parts of the world, in the tea of China and India, the coffee of Arabia, the cacao of Central America, the maté of South America, and the guarana of Brazil. Guarana is a nervous stimulative and restorative.

An attempt is again being made, with hope of success, to work the quicksilver mine of Punitaqui, in Ovalle Department, Chile. It was worked for the crown in the Spanish times, but the war of Independence and the Indian incursions stopped it, as the latter did again in 1830.

THE BRITISH ASSOCIATION

SECTIONAL PROCEEDINGS

Section A.—Mathematical and Physical Science

On the Temperature of the Air at four feet, twenty-two feet, and fifty feet high.—J. Glaisher, F.R.S. In his opening remarks, Mr. Glaisher spoke of the erroneous opinions which were entertained previous to his balloon ascents with regard to temperature at different heights; it was supposed that the temperature of the air always decreased from the earth upwards, and followed some constant law; this was, however, found not to be the case; and in the Report to the British Association at Nottingham, in 1866, the conclusions were, "that the law of decrease of temperature with increase of elevation was variable throughout the day, and also in different seasons of the year; that at about sunset the temperature was sensibly the same up to 2,000 feet; and that at night (conjectures from the results of the observations taken in the only two night ascents) the temperature of the air increased from the earth upwards." It was therefore evident that a very large number of ascents would have to be made to determine the real laws.

Fortunately, in the second year of the balloon experiments, he placed a dry and wet bulb thermometer at the height of 22 feet above the ground, readings of which have been taken four times daily, viz. at 9 P.M., noon, 3 A.M., and at 9 P.M. Although from these observations, and also from those made at the different ascents, it was known that sometimes readings at the higher point were above those at 4 feet from the ground, no particular attention was paid to the above readings until after the results of the observations made in M. Giffard's Captive balloon were known; these, however, were of such importance, proving that "the decrease of temperature with increase of elevation had a diurnal range, and was different at different hours of the day, the change being greatest at mid-day, and least at or about sunset (see Report to the B. A. for 1869 at Exeter), and that sensible changes occurred within 30 feet of the earth," that Mr. Glaisher caused the observations taken at the height of 22 feet to be reduced; collecting the observations recorded during the period 1867-1870, the differences between the readings of the two thermometers were taken, and affixing the sign *plus* (+) to the difference when the temperature at the higher elevation exceeded that at the lower, and the sign *minus* (–) when *vice versâ*.

On taking the monthly means of these differences, it was proved that the *mean temperature* of the air at 22 ft. high differs from that at 4 feet by :—

	9 A.M. deg.	Noon. deg.	3 P.M. deg.	9 P.M. deg.
In January	+ 0·5	+ 0·2	+ 0·4	+ 0·6
,, February	+ 0·2	0·0	+ 0·4	+ 0·5
,, March	— 0·3	— 0·2	0.0	+ 0·4
,, April	— 0·6	— 0·5	+ 0·2	+ 0·5
,, May	— 0·6	— 0·4	— 0·4	+ 0·5
,, June	— 0·8	— 0·9	— 0·6	+ 0·8
,, July	— 0·8	— 0·8	— 0·8	+ 0·7
,, August	— 1·0	— 0·5	— 0·1	+ 0·9
,, September	— 1·0	— 0·6	0·0	+ 0·7
,, October	— 2·2	— 0·1	+ 0·6	+ 1·0
,, November	+ 0·2	+ 0·1	+ 0·6	+ 0·8
,, December	+ 0·5	+ 0·3	+ 0·4	+ 0·4

Therefore the monthly mean temperature of the air at 22 feet was higher than at 4 feet, at all hours of the day and night, in January, February, November, and December; in the afternoon and during the night hours in the months of March, April, August, September, and October; in the evening hours and during the night, in the months of May, June, and July; and that the results in one year agreed very closely with those in the same months in other years.

By selecting the largest number with a + sign, and the largest with a — sign in each month, it was found that in the winter months the temperature at 22 feet high ranged from 2° to 4° above, and from 1° to 2° below that at 4 feet, and in the summer months from 4° to 5° above and from 4° to 5° below that at 4 feet high.

The ratio of — readings to + was, in January and February as 1 to 5 at all hours. In March, April, August, and September, during the day, one of equality. In May, June, and July, as 3 to 2 during the day hours. In October, as 1 to 4; in November, 1 to 7; and in December, as 1 to 10. At the hour of 9 P.M. throughout the year, it was as 1 to 7.

Thus the — sign preponderates, indicating lower temperature above, during the day hours, in the months of May, June, and July; the two signs are about equal in number in the months of March, April, August, and September, and the + sign preponderates, denoting higher temperature during the day and night, in January, February, October, November, and December, and during the night throughout the whole year.

A second thermometer, carefully protected from radiation, was placed in the middle of the year 1869 at the height of 50 feet, and since then its readings have been regularly taken.

The *mean monthly temperature* of the air at 50 feet high was found to differ from that on the ground as follows :—

1869	9 A.M. deg.	Noon. deg.	3 P.M. deg.	9 P.M. deg.
In October	+ 0·2	— 0·5	+ 0·7	+ 1·5
,, November	+ 0·6	+ 0·5	+ 0·8	+ 1·4
,, December	+ 0·9	+ 0·3	+ 0·5	+ 0·5
1870				
,, January	+ 1·1	+ 0·3	+ 0·7	+ 0·9
,, February	+ 0·1	— 0·3	+ 0·3	+ 0·5
,, March	— 0·3	— 1·8	— 0·7	+ 0·7
,, April	— 0·9	— 2·2	— 1·7	+ 1·4
,, May	— 2·4	— 3·6	— 2·8	+ 1·1
,, June	— 2·4	— 3·8	— 3·1	+ 1·1
,, July	— 1·8	— 2·9	— 2·8	+ 1·1
,, August	— 1·7	— 2·7	— 2·0	+ 1·7

Thus we have the unexpected results that the *mean monthly temperature* of the air at 22 feet and at 50 feet high is higher during the evening and night hours throughout the year than at the height of 4 feet, and also higher night and day during the winter months.

In conducting the above investigation, it was known that the clouds had great influence on the temperature; Mr. Glaisher therefore selected those days with a sky covered with dense clouds, and it was found that there was on such days no difference between the temperature at the heights of 4, 22, and 50 feet. At the height of 50 feet, in the summer months, the temperature during the day was frequently 6° or 7° lower, and at night 5° or 6° higher than at 4 feet.

Section B.—Chemical Science

Experiments on the Preservation of Building Stones.—Prof. A. H. Church, M.A.

This paper gave a brief account of a process for preserving stone in which solution of monocalcic phosphate, barium hydrate, and dialysed silica are successively employed. Very numerous and extensive experiments have been made with this process upon public and private buildings. The New Midland Terminus, St. Pancras, has been treated with these solutions, and so have the Chapter House, Westminster, and portions of Canterbury Cathedral and the Houses of Parliament. The process is now the property of the Patent Concrete Stone Company.

Contributions to Mineralogical Chemistry.—By Prof. Church, M.A.

The author gives an account of his researches into the constitution of numerous mineral species. The paper gives a list of the nine species which he has discovered, including the rare cerium phosphate from Cornwall. The paper also contains the chief results which its author has obtained in the analyses performed by him during the last seven years with a view to the revision of the formulæ of the mineral phosphates and arseniates. References to the original memoirs are given under the description of each mineral. Prof. Church lays great stress, in the prefatory remarks to his paper, on the importance of ascertaining the hygroscopic water of minerals, and of obtaining the samples for analysis in a state of freedom from admixture by foreign and intruding bodies.

Section D.—Biology

Department of Zoology and Botany

Prof. Huxley, President of the Association, read a paper on the relations of *Penicillium*, *Torula*, and *Bacterium*, in which he showed the extreme probability, if not amounting to absolute demonstration, perhaps going as far towards it as the extreme difficulty of the investigation of the subject admitted, that these two latter forms were but stages of the first. Prof. Huxley gave an account of his experiments and researches, which were carried on with extreme care, and mentioned that he had become convinced that the movements of the minute germs so much alluded to by experimenters was to be accounted for by the explanation that it was the well-known Brownian movement. The bearing of this important paper seemed to be to account for the presence of Bacteria on more ordinary principles than those of spontaneous generation.

Mr. A. W. Bennett read a paper on the *Theory of Natural Selection, looked at from a Mathematical Point of View.**

Prof. Huxley paid a high compliment to the author of this paper, which he said was the first that he could recollect having heard read at Section D, which, taking up the side against Mr. Darwin, still did so in a proper and philosophic manner. He had often mentioned objections that had struck him to Mr. Darwin, who always, however, had ready a quiver full of facts which generally settled the question, and he thought it probable that when Mr. Darwin read Mr. Bennett's paper, he would have a few facts ready which might alter his view of the case.

Dr. Anton Döhrn read a paper on the *Foundation of Zoological Stations.* In this he insisted on the importance of there being zoological stations throughout the world, just as there now were meteorological and astronomical stations. The author mentioned that he had commenced at his own cost the establishment of one such station at Naples. In it he would have large and small aquaria, a constant flow of salt water, microscope rooms, and there would be a resident working zoologist, a library, and a series of bed-rooms for foreign naturalists. At this station, not only would collections of living marine animals be made for purposes of study and for supplying the aquaria of Florence, Berlin and Vienna, but a collection in spirits would also be kept to supply working zoologists at a distance with the means of research. The President of the Section, Professors Newton and E. Perceval Wright, spoke strongly in favour of the station to be established at Naples, and expressed the hope that perhaps at some future day others would be established at such outposts as Dingle in Ireland, Aden in the Red Sea, &c. &c.

Dr. J. Barker read a paper in which he described an interesting little Infusorium called *Pleuronema doliarium.*

Professor Dickson read notes *On the Embryo of the Date Palm.* The author criticised the descriptions given in the books where the slit of the cotyledon is represented sometimes as a transverse fissure near the upper part of the cotyledon (Schnizlein's Iconographia), or as a vertical one near the upper part (Le Maôut and Decaisne). Dr. Dickson described the slit as a vertical one, situated near the base of the cotyledon, and called attention to the fact that there was here no fixed relation between the medial plane of the cotyledon and that of the seed, an exception to the general rule for monocotyledons, as laid down by Hofmeister, to the effect that in vertical seeds (erect or pendulous) the medial plane of the cotyledon coincides with that of the seed, while in horizontal seeds the plane of the cotyledon is at right angles to it.

Mr. Tyerman exhibited drawings of a young healthy plant of the double cocoa-nut (*Lodoicea sechellarum*), which he had succeeded in growing at the Botanical Gardens, Liverpool. He mentioned that he had some difficulty in keeping the strangely elongated basal portion of the cotyledon from penetrating too deeply into the ground, but after it had grown to a distance of some two feet, the germ developed a single sheathing leaf, and then shortly afterwards two of the ordinary characteristic leaves of the plant made their appearance.

Profs. Balfour and Wright congratulated Liverpool on having such an interesting collection of plants as that they had seen at their Botanical Gardens, and on having so able and intelligent a curator as Mr. Tyerman, and hoped that when next they visited Liverpool they would find at the gardens a range of glass worthy of the gardens and of the most interesting collection of plants at present preserved in a few tumble-down houses.

On the Staperaythr Whale of the Icelanders.—Mr. Bird.

On the Affinities of the Sponges to the Corals.—Mr. W. S. Kent. The author criticised the views of Haeckel.

On the Effects of the Pollution of Rivers on the Supply of Fish.—Sir James Alexander. This paper gave rise to a lengthened discussion.

Mr. Moore, director of the Liverpool Museum, exhibited some of Captain Mortimer's Sea Aquaria, by means of which he had been enabled to transport from the tropics many delicate marine fishes, crustacea, and sea anemones. He also exhibited a young Lamatin and the jaw of a fish, the rami of the mandible of which, instead of being united by a ligamentous union and forming a bony symphysis, were most compactly hinged together, admitting of a considerable amount of lateral motion. Mr. Moore also exhibited a stuffed skin of that most wonderful shark from the Seychelles, called *Rhinodon typicus.* This was the only perfect specimen known in any museum. This shark, which grows to the length of 50 feet and upwards, was known to Mr. Swinburne Ward, late Civil Commissioner of the Seychelles, as common off those Islands. But it was not known to be described until identified by Prof. E. Perceval Wright as the *R. typicus* of Smith.

A Statement in Reply to two Objections of Prof. Huxley relative to certain Experiments.—Dr. Bastian.

Department of Anatomy and Physiology

On Some of the more Important Facts of Succession in Relation to any Theory of Continuity.—Dr. Cobbold. This paper—which by permission had been transferred from the Department of Zoology and Botany—Dr. Cobbold stated, was generally of an elementary character. He said that for several years past the Biological Section of the Association had permitted, if it had not actually encouraged, the reading and discussion of papers having for their object the popularising (or it might be the unpopularising) of the theory of natural selection. To many besides himself the separate papers and remarks which followed were eminently unsatisfactory, perhaps arising not so much from any want of ability on the part of the authors as from the unscientific method adopted by them. The discussion which followed the reading of the Rev. F. O. Morris's paper at Norwich, "On the Difficulties of Darwinism," was lamentable in the extreme; for, so far as could be gathered, not one of those who sympathised with the reverend gentleman's position had the courage to advance a single fact in favour of the view which his "difficulties" were intended to support. At Exeter Mr. Morris renewed his exposition, but a much more vigorous effort in the same direction was made by the Rev. A. Freeman. The severity of the criticism which followed these final literary efforts in aid of anti-evolutionism could only be understood by those who were present; but the general conclusion of scientific authorities was significantly expressed in the statement made more than once to the effect that "neither of the papers ought to have been read." For his part, he thought the utmost freedom should be allowed to all desirous of opposing this or that theory; yet it should be thoroughly well understood that the sectional committee deprecated the employment of quotations from the Scriptures calculated to excite religious prejudice. A purely scientific question could only be satisfactorily discussed on a scientific basis—unless, indeed, it was insisted that theological speculations were inseparable from the domain of science. He then went on to say that to the mass of so-called educated men the acceptance of the views set forth by Mr. Darwin in his work "On the Origin of Species" must naturally present a variety of difficulties, and it appeared to him (Dr. Cobbold) that the best and truest way of showing an intelligent sympathy with those who were so situated, was to select and present some natural group of observed facts in such a clear and, if possible, attractive light, that common sense alone might be trusted to recognise the reasonableness or otherwise of honestly asserted deductions. The facts he had selected for exposition were such as represented what might be termed the apparent chronology of the organic series, or, in other words, the ascertained times of the coming and flourishing of the larger animal groups. A true conception of what was or ought to be understood by the expression "equivalences"—botanical, zoological, or geological—lay at the very basis of a correct appreciation of the significance of the records of animal, vegetable, or sedimentary rock distribution throughout all time. Further, he ventured to assert that the grandeur of the formative scheme of nature, whether testifying to an evolutionary method of production or to a series of creative acts, few or many in number, could only be adequately realised by the naturalist whose powers of allocation and grouping enabled him to grasp the magnitude and infinite import of those relations. Dr. Cobbold said he had insisted upon equivalency for years past. He then proceeded to deal with the facts of succession, and said the earliest organism as regarded time which geology had revealed was the fossil called Eozoon, which belonged to the lowermost division of the animal series. Dr. Cobbold then described the succession of the various known groups, and, glancing at the times of origin and suc-

* This paper will be found in full at p. 30.

cession of the placental mammals, said the first thing that the record suggested was the rapidity with which the most divergent groups made their appearance. Of course, there was no real basis for an assumption of a coeval creation, so to speak. It might be fairly held, on zoological grounds, that we ought not to separate man and monkeys, but retain them as one of the twelve groups under the ordinary title of primates. He adopted the division of the placental into twelve groups, not from any rigid belief as to their separate equivalences, but because they were not only sufficiently distinctive for all practical purposes, and also formed on the whole perhaps the finest expression of grouping which science could at present afford. After dwelling at great length upon the succession of the various groups, he stated that as regarded the highest of all, the placental series, he would only say that, as he understood the doctrine, the strictest demand of the development theory did not require, as was too commonly supposed, a lineal descent as between bimana and quadrumana; but it was certainly held that either of these groups, as we now knew them, might have been separately evolved from more generalised primatal types, the intermediary terms being possibly connected by a long antecedent and far more generalised common progenitor. In that connection the most advanced evolutionist must candidly own that the assumedly missing tertiary primatals constituted a great and very natural bar to the complete and popular acceptance of the theory of descent by natural selection. On the other hand, the scientific naturalist, whilst admitting these serious deficiencies, threw into the opposite scale a multitude of considerations, the collective value of which seemed to him to outweigh all the data thrown into the anti-continuity side of the balance. For himself, in conclusion, he said that his necessarily limited application of those data was amply sufficient to enforce upon him the provisional acceptance of any theory of continuity. To his mind, its clear application irresistibly implied that nature, to use an old phrase, was but a series of harmonies—wheel within wheel, there being probably but one wheel differing only from all the wheels of whose limits it was not possible for them to conceive. However, in the contemplation of the phenomena presented to them within that wheel—or that realm of "orderly mystery," as the president had called it—there was ample room and verge for the display of the highest physiological attributes with which man was endowed.

Department of Ethnology and Anthropology

The report *On the Heat Generated in the Blood in the Process of Arterialisation*, by Dr. Arthur Gamgee, was taken as read.

New Physiological Researches on the Effects of Carbonic Acid.—Dr. B. W. Richardson. The author explained that the observations he had made were new in that they related to the direct action of carbonic acid on animal and vegetable fluids, and they were interesting, equally to the zoologist and botanist as to the anatomist. The author first demonstrated the result of subjecting a vegetable alkaline infusion to the action of carbonic acid under pressure. The result was a thick fluid substance which resembled the fluid which exudes as gums from some trees. When the fluid was gently dried it became a semi-solid substance, which yielded elastic fibres. This observation had led the author to study the effect of carbonic acid on albumen, serum of blood, blood itself, bronchial secretion, and other organic fluids. When the serum of blood was thus treated with carbonic acid under pressure and general warmth, 96° F., the collodial part was separated; but when the blood, with the fibre removed from it, was treated, there was no direct separation, the blood corpuscles seeming for a time to engage the gas by condensation of it. But blood containing fibrine, and held fluid by tribasic phosphate of soda, was at once coagulated by the acid. The bronchial secretion is thickened by carbonic acid, and a tenacious fluid is obtained, resembling the secretion which occurs in asthma and bronchitis, while secretions on serous surfaces are thickened and rendered adhesive. After details of many other facts, Dr. Richardson concluded by showing what bearing this subject had of a practical kind. In the first place, the research had relation to the question of elasticity of organic substances; and, secondly, on the direct action of carbonic acid in the production of vegetable juices. But the greatest interest concentrated on the relation of the research to some of the diseases of the animal body. Thus in instances where the temperature of the body is raised and the production of carbonic acid is excessive, the blood on the right side of the heart has its fibrine often precipitated, and in many other cases fibrinous or albuminous exuded fluids are solidified, as is the case in croup. The author, in the course of his paper, explained how rapidly blood charged with carbonic acid absorbed oxygen when exposed to that gas, and he held that carbonic acid in the venous blood was as essential to the process of respiration as was the oxygen in the pulmonary organs.

SCIENTIFIC SERIALS

Journal of the Chemical Society, October, 1870.—The first paper in this number is by Dr. Divers, "On the Precipitation of Solutions of Ammonium Carbonate, Sodium Carbonate, and Ammonium Carbamate by Calcium Chloride." These results obtained by Dr. Divers are the following:—Calcic carbamate is soluble, and the presence of ammonia retards its transformation into carbonate. When carbonic anhydride is passed into an ammoniacal solution of calcic chloride, the carbamate is first formed, and is gradually precipitated as carbamate. This paper is followed by nearly two pages of Addenda et Corrigenda to the author's previous memoir.—"On the Manipulation of Gold and Silver Bullion," by Charles Tookey, Assayer in the Japanese Imperial Mint, formerly in the Royal Mint, Hong Kong. In this paper the author gives descriptions of two of the processes that he has adopted. Instead of boiling the cornets in separate parting flasks, he uses a series of perforated platinum tubes, supported in a porcelain plate. A number of cornets are, by this means, simultaneously submitted to the action of the nitric acid. Secondly, in order to clean the buttons, they are placed with the lower side uppermost on a platinum plate with depressed perforated cavities, which is plunged into hot dilute hydrochloric acid, afterwards into hot water acidulated with hydrochloric acid, and lastly into pure water. The plate is then drained by placing it on porous paper and dried over a gas flame.—"On some new Bromine Derivatives of Coumarin," by W. H. Perkin, F.R.S. On adding coumarin to bromine in the presence of carbonic disulphide, allowing the solution to evaporate, and crystallising the residue from alcohol, dibromide of coumarin $C_9H_6O_2Br_2$ is obtained. When coumarin and bromine in carbonic disulphide are digested at 140°, bromo-coumarine $C_9H_5BrO_2$ and dibromo-coumarin $C_9H_4BrO_2$ are produced, and are separated by crystallisation from alcohol, in which the latter is the less soluble. Dibromo-coumarin fuses at 174°, and distils nearly unchanged. It crystallises from alcohol in small needles. Bromo-coumarin fuses at 110°, and crystallises from alcohol in transparent prisms, often beautifully curved. When heated with solution of potassic hydrate both the bromo-compounds dissolve, producing crystalline salts, probably containing the bromo-coumaric acids.—"On Organic Matter in Water," by Mr. C. Heisch. The author has observed that certain waters which are known to be contaminated with sewage matters, give rise to the formation of a microscopical fungus when a small quantity of sugar has been added, and the mixture exposed to light for a few days at the temperature of 60°-70° F. Six drops of sewage from which the solid matter had settled, were mixed with 10,000 grains of West Middlesex and New River water; to 6 oz. of the mixture 10 grains of pure sugar were added, and 10 grains were also added to 6 oz. of the water without sewage; these solutions, and some of the mixture of water and sewage, were placed at a window. The water containing the sewage and sugar became turbid in 24 hours, the other liquids remaining clear. On examining the turbid water with an ⅕ inch object glass, it was found to be filled with small spherical cells, with, in most cases, a very bright nucleus, which group themselves in bunches like grapes; they then spread into strings, with walls surrounding and connecting the cells; the original cell walls afterwards break, leaving tubular threads branched together. After several days, an odour of butyric acid is perceived. One drop of fresh urine in 10,000 grains of water produced similar effects; though without the addition of the sugar, the water might be kept for weeks without becoming turbid. Filtration through Swedish paper, or boiling for half an hour, does not prevent the growth of the fungus. The water no longer exhibits this property, however, after passage through a good bed of animal charcoal, that is, if the charcoal is frequently exposed to the air. If the filtration is continuous, the filtrate soon becomes as bad as the original water.—"On the Methods for the Determination of Carbon in Steel," by Mr. W. D. Herman. The author has obtained very concordant results by burning the iron or steel in a current of oxygen, the iron is converted into ferric oxide and the carbonic anhydride collected in potash bulbs and weighed. Some results obtained by four different methods of estimating the carbon in iron and steel are given at the conclusion of the paper.—"On the Determination of Phosphoric Acid," by Mr. W. C. Williams. The author suggests a modification of the process for separating phosphoric acid from the alkaline earths originally proposed by Reigsig.

SOCIETIES AND ACADEMIES

BRISTOL

Observing Astronomical Society.—Report of observations made during the period from Aug. 7 to Oct. 6, 1870, inclusive.

Solar Phenomena.—Mr. Thomas G. E. Elger writes:—The magnificent display of solar spots observed in August was repeated, though in a rather less striking manner, during September. Between the 7th and 12th the spots were small, few in number, and mainly confined to the S. hemisphere; on the 11th only three moderately-sized groups were visible. The immense group observed last month, and which was near the centre of the disc on August 30, was due at the E. limb about the 17th, but owing to unfavourable weather and absence from home, I did not notice it till the 24th, when it measured 2′ 45″ × 1′ 50″ without including the outlying penumbra which followed it; its length on the 25th was 3′ 0″. The penumbra of this group presented some remarkable features. It contained four large umbræ and many smaller ones; on the preceding side it was thickly studded with minute dots of every shade from black to light brown. When examined with a power of 180 at 3^h on the 25th, the entire group was evidently undergoing rapid and violent changes, the striation of the penumbra and the dark "spurs" and serrated edges of the umbra clearly indicating the cyclonic nature of the forces involved. The above group was preceded by a very long and narrow V-shaped spot, which occupied nearly the same position as a large spot observed in August. Several other groups were observed during the month, which presented interesting details, but they were generally smaller than the August groups. The appearances exhibited by the large group described above, and indeed by most spots of a similar class observed this year, seem altogether opposed to the "deep excavation" theory of sun spots.—Mr. T. W. Backhouse, of Sunderland, reports "a very fine group of spots passed the sun's centre in the northern zone on September 21; on Sept. 23, at $21^h\ 15^m$, it contained two very long penumbræ, which were not widely separated; the *f* one was 74,000 miles long, and the *p* one 92,000! On the 25th, at $19^h\ 45^m$, it was only 66,000 miles long, and the *f* penumbra was divided into two. Another very fine group, also in the N. zone, passed the sun's centre on the 24th. The dimensions in miles of its chief spot were as follows:—

Date.		Time.	Penumbra. Length.	Penumbra. Width.	Umbra. Length	Umbra. Width.
Sept.	21	$5^h\ 15^m$	——	47,000	26,000	11,000
	,,	$21^h\ 25^m$	abt. 72,000	50,000	31,500	——
	22	$3^h\ 25^m$	50,000	——	29,500	——
	23	$21^h\ 25^m$	63,000	——	——	——
	25	$21^h\ 30^m$	abt. 70,000	——	——	——

On the 23rd, at $4^h\ 40^m$, I found it was divided into four, apparently by a violent current in the middle from *p* to *f*".—Mr. William T. Dunning, of Bristol, observed the large spot visible on September 21; with his 4-inch metallic reflector he could very distinctly see a black nucleus in the S part of the umbra. It did not appear to be actually enclosed within the umbra, but was situated on the margin of the penumbra.—Mr. E. B. Knobel, of Burton-on-Trent, says that on Sept. 25 the large group near the centre of the disc measured 2′ 54″ by 1′ 44″; on the 26th the two largest groups were equal in length to 2′ 44″ and 2′ 36″ respectively. They were distinctly visible to the naked eye.—The Rev. S. J. Johnson, of Crediton, writes that on September 21, at $4^h\ 30^m$, a power of 70 on a 2½-inch *O.G.* showed penumbræ on, at least, 26 spots visible on the sun. On September 20 "seven spots were very large indeed, and arranged in five groups, each scattered over a large surface."—Mr. Albert P. Holden, of London, referring to the large spot, says that on September 20, "when entering on the solar disc it appeared as an elongated spot with a bright arm stretching over half the umbra till it joined a projection on the N. side. It was followed by a large broken group of broken masses of various dimensions. On the 23rd, at 8 A.M., the chief spot had enlarged considerably, while the broken ones following it had very much decreased. The great spot was very nearly divided into two by a very broad arm springing from the N.; the W. portion of the umbra being again subdivided by a similar arm on the S. side. This last was on one side broken up very peculiarly, so that it presented the appearance as if a handful of bright straw had been thrown carelessly upon it. The eastern portion of the umbra was crossed by a very bright curved streak, which was so bright and so clearly distinct right up to its edges as to appear more like a carved piece of silver. On the 24th, at 8 A.M., the broken mass before referred to as following the chief spot had almost disappeared, with the exception of one small spot and a small amount of penumbra. The great spot was also a little smaller and quite divided by the broad arm. A large crack appeared in this latter. Each of the two portions of the original spot were also divided by luminous bridges across them. On the 28th the appearance of the umbra was much the same, although the penumbra was entirely changed and a great narrow branch had projected S. to an immense distance. This great arm was dotted here and there with a few patches of umbra. The broken mass which had followed the great spot at its first appearance was now entirely dissipated. On the 29th the two portions of the original spot were widely separated and much contracted, and two spots to the S. which had hitherto been of very small size much increased in dimensions. The rotation of the solar orb then carried the spot out of sight. The principal fact impressed upon the mind by these observations is that a spot becomes dissipated in consequence of its continual division and subdivision by the projection of luminous bridges across its various portions.

DIARY

THURSDAY, NOVEMBER 10.

LONDON INSTITUTION, at 7.30.—Acoustics of the Orchestra: Dr. W. H. Stone

LONDON MATHEMATICAL SOCIETY, at 8.—Annual General Meeting. Recent Researches on Quartic and Quintic Surfaces: By Prof. Cayley.—The Retiring President's Address.

FRIDAY, NOVEMBER 11.

ASTRONOMICAL SOCIETY, at 8.

MONDAY, NOVEMBER 14.

LONDON INSTITUTION, at 4.—Chemical Action: Prof. Odling.

TUESDAY, NOVEMBER 15.

ANTHROPOLOGICAL SOCIETY, at 8.—Observations on the Condition of the Blood-Corpuscles in Certain Races: Dr. R. H. Bakewell.—Tribal Affinities among the Aborigines of Australia: Mr. C. Staniland Wake.—Description of Australian Aborigines and Half-Castes, with Exhibition of Skulls: Dr. Robert Peel.

ZOOLOGICAL SOCIETY, at 9.—On the Form and Structure of the Manatee (*Manatus Americanus*): Dr. J. Murie.—Observations on the Salmonidæ in Tasmania: Mr. Morton Allport.—On the Anatomy of *Ailurus fulgens*: Prof. Flower.

STATISTICAL SOCIETY, at 7.45.—On the Claims of Science to Public Recognition and Support, with Special Reference to the so-called "Social Sciences": Dr. Guy, F.R.S

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.

THURSDAY, NOVEMBER 17.

LINNEAN SOCIETY, at 8.—On the *Passifloreæ*: Dr. M. T. Masters.—On the White-beaked Bottle-nose: Dr. James Murie.

CHEMICAL SOCIETY, at 8.—Mineralogical Notices: Prof. N. Story Maskelyne and Dr. Walter Flight.

LONDON INSTITUTION, at 8.30.—Acoustics of the Orchestra; Wind Instruments: Dr. W. H. Stone.

THURSDAY, NOVEMBER 17, 1870

THE PRESENT EPIDEMIC OF SCARLET FEVER

THE prevalence of scarlet fever at this time throughout England and Wales is a question that not only affects medical men, but is one that demands the attention of the people of England. They ought to ask themselves the question as to how it is that a malady which is placed by medical writers under the class of "preventible" diseases is allowed to prevail to the extent of destroying several hundreds of persons weekly. Scarlet fever seems to enjoy that immunity which is accorded to what are called "necessary evils;" but when we come to inquire what right this disease has to carry off ten or twelve thousand persons annually, we find that it ought no more to exist amongst us than small-pox or cholera.

Scarlet fever is essentially a contagious disease, and exhibits all the phenomena of a malady which, being communicated from one individual to another, is more or less under the control of human action. Under these circumstances, it is impossible for the Government to stop such a disease by mere Acts of Parliament, or for medical men to superintend efficiently arrangements for the prevention of its spread. It is only by the intelligent apprehension on the part of the public who are infected, that any hope of the arrest of the disease can be expected. We therefore take this opportunity of addressing the public on the subject. Unless heads of families and the public generally are acquainted with the real nature of this disease, no external organisation of any kind is sufficient for its control.

We need not refer here specifically to the returns of the Registrar-General, to show how fearfully prevalent scarlet fever has been. In London the weekly mortality has been as high as one hundred and ninety in a week, giving a mortality for London alone of nearly ten thousand a year. Professor Huxley, in his late address at Liverpool as President of the British Association, says that in the years 1863, 1864, and 1869, 90,000 persons were killed in England and Wales by scarlet fever. These figures point to a much higher mortality for scarlet fever than we have ever had to record for cholera. The point most remarkable about this mortality is, that whilst death from cholera has agitated every British community, no public anxiety has been manifested about scarlet fever. Every one has submitted to it as a necessary evil, and no one has made any efforts to diminish its prevalence.

Yet, when we come to inquire into the nature of scarlet fever, and the laws of its distribution, there seems to be no more reason why it should prevail amongst us than plague, small-pox, or cholera, whose laws of distribution we now know, and on which we can exert the most obvious control. Scarlet fever is a contagious disease, and it is not too much to say that we have *all contagious diseases under our positive control.* Their nature, and the laws of their distribution, are so well known, that it is possible to teach the humblest individual interested in their destruction the means by which it may be effected.

We need not here enter into the discussion of the nature of "poison germs," of "microzymes," or other ultimate forms which the poisons of contagious diseases may assume, but we may affirm that in every body affected with scarlet fever there is produced poisonous matter, which, passing from the diseased body, is capable of generating anew the same disease as that which affects the body from which it is derived. The proofs of this are so abundant that we cannot for a moment admit that the question is open to discussion. The point of most importance here is to know how long the "poison germs" of scarlet fever retain their vitality—the terrible power of starting anew the changes of which they are the offspring. With regard to scarlet fever, we have more evidence of these "poison germs" retaining their vitality than with many other contagious diseases. Sir Thomas Watson, in his classical lectures on the "Practice of Physic," mentions a case in which a piece of flannel worn round the neck of a scarlet fever patient, being accidentally discovered two years after, and applied to the person of a servant in the family, produced an attack of scarlet fever. Were it necessary, I could mention several instances coming within my knowledge and reading, of the scarlet fever poison lying dormant in woollen clothes for years, and not having lost its vitality, or power of communicating the disease.

Another point of importance with regard to the scarlet fever "poison germs," is the length of time which a person once affected with scarlet fever is capable of communicating the disease to others. When a person has got well of scarlet fever as far as general health goes, it is by no means the case that he is no longer capable of communicating the disease, but many days after he is strong and apparently healthy, he is capable of disseminating "poison germs" from his body. A recent instance has been recorded in one of our medical journals, of the prevalence of scarlet fever in families supplied from the milk of a particular dairy. On searching inquiries being made, it was found that the persons connected with the farm from which the milk was supplied, had been affected with scarlet fever. Although they had not been allowed to milk the cows till they had recovered from the scarlet fever, it was, nevertheless, found that they had been engaged in this occupation whilst the effects of scarlet fever in the desquamation of the cuticle of the skin was still going on. There are abundant other examples on record to show that until the desquamation of the cuticle which always follows scarlet fever is complete, no person who has had scarlet fever is safe from giving it to others.

Such then being the nature of the poison of this disease, what ought to be known in families where it breaks out, and what to be done as the result of this knowledge to prevent its spread? It is no use saying that the doctors will give all necessary directions. In the first place, it may be said that the doctor in nine cases out of ten will not give any directions at all. It is not his interest to do so; and if it were, he gets no information in his books or lectures on the subject at all. The medical profession is not required by its governing or examining bodies to know anything about public health or preventive medicine. In the next place, however admirable may be the directions of medical men, persons utterly ignorant of the nature of disease will fail to carry out the simples directions given to them. Nothing can be a substitute for a knowledge of the first principles involved in the destruction of "poison germs" in a family attacked with contagious disease.

What, then, ought to be done in a family when scarlet fever, or any other contagious disease, has broken out? In the first place, the entire isolation of the persons attacked should be secured. They should either be removed to a room in the house to which none but the nurse and doctor have access, or the family should be removed to some house of refuge or place where the disease does not exist. It may be urged that this cannot be done; but if it be a mere question of expense, it should be considered whether the cost of the deaths, the funerals, and the doctor's bills of a family of several children, and perhaps the father or mother, may not really, in a money point of view, be greater than any cost of isolation.

But whether isolation is attempted or not, there is another set of facts which must be borne in mind. The "poison germs" of which we have spoken can really be destroyed. If left alone they can lead a life of poisonous activity. We have the means of killing them—poisoning them in their birth, as it were—by certain substances whose properties we well know. We cannot here write a history of disinfectants, but they are well known, and the advertising sheets of every newspaper will afford information with respect to them. The most common and available are carbolic acid, permanganates of soda and potash (Condy's Fluid), chlorinated lime or soda, chloride of zinc (Burnett's Fluid), chloride of aluminium (chloralum), sulphate of iron, and others. These agents have the power of destroying the poisonous activity of scarlet fever germs. In the sick-room and around the patient they should be constantly employed. All the secretions of the person affected, whether they come from the nose, the mouth, or other excretory organs, should be immediately brought in contact with one of these agents. All linen and clothes worn by the patients should be placed in a solution of one of them. Nurses attending on the sick, and medical men touching them in any way, should not leave the room without washing their hands in one of these disinfecting fluids.

Woollen clothing that cannot well be washed should, by some agency or another, be exposed to heat. It is well known that a temperature of 212° F., the temperature of boiling water, will destroy poison germs. Woollen clothing of all kinds, such as shawls and mantles, men's clothes, as also curtains, bell-pulls, carpets, rugs, and beds, should be placed in ovens, or by some contrivance or another exposed to a heat above 212°. In St. James's, Westminster, a disinfecting apparatus has been erected in the Workhouse-yard, where the various articles mentioned can be disinfected.

Having thus indicated general principles, I must leave details. I am convinced that the holocaust of victims that we annually offer to this Moloch of scarlet fever arises from ignorance, and that a general knowledge alone of the facts above stated can suffice to drive from us this plague, so disgraceful alike to our intelligence and our humanity.

E. LANKESTER

SCHIMPER'S VEGETABLE PALÆONTOLOGY

Traité de Palæontologie Végétale. Par W. Ph. Schimper. Tome ii. Première Partie, pp. 522. (Paris, 1870.)

THE first part of the second volume of this very important work (the first volume of which was reviewed in the first number of NATURE) has just appeared, with a quarto atlas of twenty-five plates; and it maintains the high character with which it commenced. In this part the systematic description of the families, genera, and species, is carried down from *Lycopodiaceæ* to the end of Monocotyledons; and the same excellent plan is carried out, of giving under each principal group its most important botanical characters and geographical distribution, drawn from living types; thus supplementing the excessively meagre descriptions that the fossils afford, enabling the reader rightly to appreciate the strength or weakness of the evidence on which the alliances of the fossils are founded, and indicating the organs or structural points most desiderated, and to obtain which collectors should search for illustrative specimens.

The following extracts and remarks will give some insight into the general nature of this volume, and illustrate the author's views as to the relations between many of the most important existing types of vegetation and their fossil representatives or allies.

Dr. Schimper ranks the great recent group of club-mosses and their allies, *Lycopodineæ*, as a class, with four subordinate families; of which two, *Lycopodieæ* and *Isoeteæ*, are abundant at the present time; the other two, *Lepidodendreæ* and *Sigillarieæ*, disappeared before the Tertiary epoch.

Under the order *Lycopodiaceæ* he includes two families: of these (1), *Lycopodieæ*, which abounds at the present day, and inhabits all latitudes from the equator to the Arctic regions, Dr. Schimper recognises only seven fossil species, all congeneric with *Lycopodium* itself, and, strange to say, confined (with the exception of one doubtful species) to the coal measures—a most remarkable fact, if capable of confirmation; but, after making every allowance for the imperfection of the geological record, it appears impossible to admit that a group so well represented now-a-days should be absent from all intervening beds, including the most modern tertiaries; and it is a startling proof either of the vagueness of the characters by which we ally our fossils to existing types, or of the imperfection of the said record. Upon the whole, and under such suspicious circumstances, we should be rather disposed to doubt the fossils being Lycopodiums at all.

Dr. Dawson's four species of this order, from the Devonian of North America, Dr. Schimper considers not to be recognisable as such; so that, little as his own data can tell us of the fossil *Lycopodineæ*, there is a lower depth of obscurity still.

Of the second family, *Lepidodendreæ*, consisting mainly of arborescent plants, all are extinct: it includes the principal genus *Lepidodendron*, with fifty-six species, all carboniferous, and with a host of synonyms, generic and specific:—*Halonia*, *Lepidoploios*, *Knorria*, and *Ulodendron*, all well known to English palæontologists. *Lepidophylla* and *Lepidostrobi* he regards as respectively leaves and fruits of some one or other of the above.

To the third family, *Isoeteæ*, which includes some fifty or sixty quill-worts and pill-worts of the temperate regions of the globe, he attributes three fossil genera; *Isoetes* itself (tertiary), and the remarkable *Psilophyton* of Dr. Dawson, which he regards as allied to *Pilularia* and not to *Psilotum*. But here again we are confronted by the suspicious fact, that nothing resembling *Psilophyton* has hitherto occurred between the Devonian and the present epoch!

The fourth family, *Sigillarieæ*, is only known in a fossil state. *Sigillaria* is the principal genus, with eighty-three species. *Stigmaria* Schimper regards as roots, but not of *Sigillaria* only, for in a supplementary note to this genus he announces the discovery of a specimen of *Knorria longifolia* (one of the *Lepidodendreæ*), the roots of which are a *Stigmaria*, the base of the stem is his own genus *Ancistrophyllum*, and the upper part is *Didymophyllum Schottini* of Göppert; thus knocking four genera into one at a blow. Add to this the fact that the leaves and organs of fructification, now unknown or unrecognised, may represent two more genera, and that there is a suspicious look of *Ulodendron* in one point of the structure, and we have as instructive an example of the condition of our knowledge of the carboniferous flora as can be desired.

Passing from Acotyledones to Cotyledones, or flowering plants, Dr. Schimper's first class is of *Cycadeæ*. They date doubtfully from the middle of the carboniferous, allowing *Noeggerathia*, &c. to belong to this alliance; in the Permian they are pretty certainly present, and they abound in the Trias and Jura formations. Of the two tribes composing this group, the *Zamieæ*, which now extend from the Old to the New World, seem to have appeared first; both these and the *Cycadeæ* proper (which are now confined to the Old World) are found in greatest abundance in the Jurassic age, whence they decline and disappear in the cretaceous, except *Zamiæ*, of which one species persists to the middle of the Tertiary epoch.

Here again, if we hold that the geological record tells a fragment of truth, we must believe that the Cycads and Zamias, which occupy so very wide an area of the globe in the present day, and whose organs and tissues are so well suited for petrifaction, had all but disappeared from the globe during the lapse of countless ages, to reappear in numbers, and that over a most extensive area.

No fewer than thirteen genera of fossil *Zamieæ* are described, and about twenty of *Cycadeæ*, including a multitude of species; both genera and species are however very badly, if at all, defined, being most fragmentary; and Dr. Schimper was of course ignorant of Mr. Carruthers' paper on the Fossil *Cycadeæ* of the secondary rocks of Great Britain, in the twenty-sixth volume of the Linnean Transactions, which throws great light on the subject. The genus *Trigonocarpus* Dr. Schimper doubtfully regards as consisting of fruits of *Cycadeæ* (describing fifteen species), together with *Rhabdocarpus* (twenty-four species), *Cardiocarpus* (twenty-one), and *Carpolithes* (nine).

Ascending in the scale of vegetable life, we come to the great group of Conifers, which seem to have presented such remarkable facilities for petrifaction in all ages from the carboniferous onwards, and which is divided into four great sections. 1. *Abietaceæ*, with four families; *Walchieæ* and *Voltzieæ*, of very doubtful affinity, if Conifers at all, and of which the one is usually placed in *Lycopodiaceæ*, and the other in *Cupressineæ*—neither have any recent representative; *Araucariæ*, comprising four extinct genera, together with *Araucaria* itself; and *Abietieæ* proper, including *Pinus* with 101 species. All appear tertiary; many are miocene, extending from Spitzbergen southwards; and, judging from the number found in single localities, as at Armissan, it would appear that either the pine-forests of those days were, unlike the present, formed of numerous species, or, what is more probable, that the supposed specific characters are worthless. Of larch, four miocene species are enumerated; of cedars, three cretaceous; of Abies, twenty-two species, all tertiary.

2. *Taxodiaceæ* form Dr. Schimper's second order of Conifers; it includes *Sequoia* with twelve species, one of which, the well-known miocene *S. Langsdorffii*, he regards, with Heer, as "almost identical with the Californian *Taxodium sempervirens*, now confined to Mexico." In its fossil state it extends from Arctic East and West America and Greenland to Bonn, Italy, and Greece. Another existing *Taxodium*, again, contains a miocene species, absolutely identical with the living *T. distichum* of the Southern States of North America, where it forms a large proportion of the arboreous vegetation of the Great Dismal Swamp. In a fossil state this also extends from Greenland and Spitzbergen to North Italy. Two other existing genera of this group, the North Chinese *Glyptostrobus*, and the South African *Widdringtonia*, are both supposed to be found in the European miocene formations.

3. Of *Cupressineæ*, to which the modern cypress, arbor-vitæ, juniper, and the extensive genus *Callitris* of Australia belong, there are fossil types supposed to belong to recent genera; viz. of *Libocedrus*, now confined to New Zealand and South Chili, there are two Spitzbergen and a European species, all miocene; of *Thuja*, five, all found in amber beds. To the American and Japanese White Cedars (*Chamæcyparis*) two European fossils are referred. The four junipers are a very doubtful lot.

Taxaceæ, represented throughout the northern hemisphere by one living yew, in Japan by the Maiden-hair tree (*Salisburia*), and in the tropics and south temperate regions of both the old and new worlds by various species of *Podocarpus*, have been supposed to be discovered in small numbers in a fossil state. Thus, of *Salisburia*, the existing Japanese species is believed to be found in the miocene of Greenland and near Verona, and two other American species are described—all miocene. The fossil yews are all doubtful, and the *Podocarpi*—eight in all—are probably equally so.

Gnetaceæ, to which the curious existing genus *Gnetum* (tropical), *Ephedra* (temperate), and *Welwitschia* (tropical) belong, are represented by two modern species of *Ephedra*.

The volume closes with 130 pages of Monocotyledonous fossils—a very miscellaneous and for the most part exceedingly obscure assemblage. The existence of this class in the carboniferous epoch is regarded by Dr. Schimper as not proven, and more than doubtful. In the Trias it is pretty well established by *Yuccites* and *Æthophyllum*, but there is a hiatus between that age and the Jurassic, when an obscure set of water-plants and perhaps *Pandanus* occur, to be followed by another hiatus till the cretaceous epoch, when *Gramineæ*, *Cyperaceæ*, and several of the principal orders of monocotyledons appear in some force. Whether, however, we ascend or descend in the scale of vegetable life, as represented by fossil monocotyledons, we feel the generic and even the ordinal determinations of the fossils to be throughout very doubtful, and to be reducible in most cases to the category of bold guesses. To refer the majority of living and growing monocotyledons, and especially of such orders as *Gramineæ*, *Cyperaceæ*, *Naiadeæ*, *Palmæ*, and *Liliaceæ*, to their genera from their leaves alone, is impossible ; much more then from the fragmentary fossil remains of these organs. Such genera and species, however, have been made, and Dr. Schimper must sweep them into his net ; and the more ungrateful the task, the more obliged we should be to him or performing it so well and so fully.

We shall look for the Dicotyledonous volume ot this great and most useful work with much interest, and lay an account of it before our readers as soon as it appears

J. D. HOOKER

THE YOSEMITE VALLEY AND THE SIERRA NEVADA OF CALIFORNIA

The Yosemite Guide-book. By J. D. Whitney. Published by authority of the Legislature of California. 1869.

MR. J. D. WHITNEY, State Geologist of California, has prepared a guide-book to the Yosemite Valley and the adjacent country, which is a model of its kind. It is well written, and is eminently lucid in its descriptions ; it is amply illustrated, and has two clear maps on a large scale half a mile and two miles to the inch) ; and it is admirably printed (at the University Press, Cambridge, U.S.). The unpretending title of the work gives but a poor idea of its contents ; botanists, geologists, and geographers will find pleasure in reading it, although it is ostensibly put forth or the sake of the ordinary tourist. It is a valuable contribution to our knowledge of the Pacific coasts of America, and throws light upon a large district which remains very imperfectly known.

The British public has been already tolerably familiarised with the most striking characteristics of the Yosemite* Valley, Mariposa County, California, by the fine picture of Mr. Bierstadt ; and some excellent photographs (by Watkins, of San Francisco), which are now lying before us, show that that artist has not drawn upon his imagination. Some of our readers, however, may perhaps need to be told that it is not only a very remarkable valley, but boasts the possession of the highest waterfalls (with an equal volume of water) in the world. It is trough-shaped ; a cross section of it is like the letter U, and in this respect, as well as in its length, breadth, and the steepness of its cliffs, it is comparable to the Valley of Lauterbrunnen in Switzerland, but the dimensions of its cliffs exceed those of that valley, as much as its chief waterfall (the great Yosemite Fall) surpasses the Staubbach. This magnificent cascade makes a descent of more than half a mile in sheer height, and 500,000 cubic feet of water pass over it per hour during the month of June. It is made up of two falls—an upper one, which has a vertical descent of 1,500 feet, and a lower one of 400 feet. The remainder of the total height is consumed by a series of cascades between the two ; but seen from the opposite side of the valley, the effect is increased rather than diminished by the subdivision, and it well deserves all the praise which has been lavished upon it.

* The word Yosemite means a full-grown grisly bear.

Mr. Whitney does not believe that the peculiar trough form of the valley has been even modified by glacier action. There are no proofs, he says, "that glaciers have ever occupied the valley, or any part of it," and he scouts the notion that it was *produced* by glacial agency. "In short," he says, "we are led irresistibly to the adoption of a theory of the origin of the Yosemite in a way which has hardly yet been recognised as one of those in which valleys may be formed, probably for the reason that there are so few cases in which such an event can be absolutely proved to have occurred. We conceive that during the process of upheaval of the Sierra, or possibly at some time after that had taken place, there was at the Yosemite a subsidence of a limited area, marked by lines of 'fault' or fissures crossing each other somewhat nearly at right angles. In other and more simple language, the bottom of the valley sank down to an unknown depth, owing to its support being withdrawn from underneath, during some of those convulsive movements which must have attended the upheaval of so extensive and elevated a chain, no matter how slow we may imagine the process to have been." It should be mentioned that the Yosemite Valley is exclusively granite, no remains of sedimentary rocks having been found within it.

Although the Yosemite Valley itself is not ice-ground, in its neighbourhood there are very emphatic traces of glacial action, and it is said that in some places the polish is so perfect upon the rocks, that "the surface is often seen from a distance to glitter with the light reflected from it, as from a mirror." It is remarkable that no glaciers are known to exist at the present time throughout the entire length of the Sierra Nevada in California. Throughout the entire region, from 35° to 42° N. lat., Mr. Whitney asserts that there is not a single glacier. Yet Mount Shasta, at the northern extreme, with a height of pretty well 15,000 feet, is more or less permanently covered with snow upon its upper 6,000 feet, and at the southern end of the district there are numerous peaks (now being surveyed) which range from 14,000 to 15,000 feet, and even higher. We confess that we do not understand how "masses of snow, several miles long, and hundreds of feet in thickness, remain all summer without showing any indication of becoming glacier ice," if they remain permanently of these dimensions ; but as such seems to be the fact, there is no use in disputing it.

The most valuable portions of Mr. Whitney's book are those which he has devoted to elucidating the topography of the mountain ranges bordering upon, or in proximity to, the Pacific Coast. We learn from him in a clearer way than we have seen it put before, that there are two great ranges of mountains running throughout the length of California, which are orographically distinct. These he terms the Coast Ranges, and the Sierra Nevada. They are roughly parallel to each other, and to the coast line ; and they are divided by the valleys of the Sacramento and San Joaquin rivers. The coast ranges are, geologically speaking, younger than the Sierra Nevada, and they are chiefly made up of cretaceous and tertiary strata. They are also of comparatively small elevation, and their highest summits attain only 8,000 feet. The core of the Sierra Nevada, on the other hand, is mainly granitic, flanked on both sides by metamorphic slates, and has a much greater elevation.

Both of these ranges are totally distinct from the Rocky Mountains, which are hundreds of miles further inland. The only drawback to travel among them is the "poor Indian," who watches travellers from a distance, and signals by smokes. We can well understand the enthusiasm of Mr. Whitney for the mountains of California, and we heartily hope with him, that neither the Yosemite valley nor the grove of Sequoias which—by a unique act of Congress—were ceded to the State for public use, resort, and recreation, for all time, will be suffered to fall into the hands of the acute but unpatriotic speculators who are endeavouring to use them for their own purposes; and who will, if they are not "sat upon," undoubtedly turn them into "gigantic institutions for fleecing the public." W.

OUR BOOK SHELF

The Science and Art of Arithmetic: Part II. Vulgar Fractions; Part III. Approximate Calculations. By A. Sonnenschein and H. A. Nesbitt, M.A. 260 pp. (London: Whittaker & Co. 1870.)

THE authors of this excellent school arithmetic are to be congratulated on having brought their work to a successful termination. In our notice of Part I., which appeared in a former number of NATURE,* we pointed out the principles by which the authors had been guided, and as we believed those principles to be sound, and the authors to have carried them out successfully, we had no hesitation in commending the work as we did. The same good arrangement, ample store of illustration, and copious examples for practice, are to be found in this volume as had place in the first. The fulness with which the elementary portions were treated appeared to us to be a merit rather than a defect. From such wealth of illustration each teacher could select what was most suited to his purpose. In this volume we have more advanced subjects treated in like manner. But an analysis of the contents will give a good idea of the work. Under Part II. we have the subject of Vulgar Fractions clearly treated, with applications to Practice, and a chapter which treats of Proportion, the Chain Rule, Compound Proportion, and Proportional Parts. In Part III. are chapters on Converging Fractions, Decimals with their properties, and several applications to Money, Weights, Measures, &c., the Metric System, Progressions, Interest, Discount, Stocks, Evolution, and a good chapter on Arithmetical Complements. There is also a chapter in which we have Continued Product to a given limit, Compound Interest, Equation of Payments, Complex Decimals, Duodecimals, and International Calculations. At the end of the work are given 250 Miscellaneous Exercises. There is enough here to satisfy any youthful arithmetician, and the methods employed are the "latest out." The complete work gives ample evidence that it is the composition of men who have given much time and thought to the subject, and have had much tuitional experience. R. T.

Die Schmetterlinge Deutschlands und der Schweiz, systematisch bearbeitet. Von H. von Heinemann. Zweite Abtheilung, Kleinschmetterlinge. Band II. Die Motten und Federmotten, Heft 1. 8vo. (Brunswick: C. A. Schwetschke and Son, 1870.)

M. HEINEMANN'S work on the Lepidoptera of Germany and Switzerland is well known to entomologists, by whom it is highly valued. It contains an admirable systematic description of the species of butterflies and moths inhabiting the above-mentioned countries, and has been carried out by the author in so conscientious a manner that the students of European Lepidoptera can hardly wish for a better handbook. The author is now approaching the conclusion of his labours. The first section, including the larger forms of Lepidoptera, was completed some years ago; of the second section, the first volume, published in 1863 and 1864, contained the descriptions of the Tortrices and Pyralides, and the part now before us commences the true Microlepidoptera, the Tineæ and Pterophori. The former are exceedingly numerous, and the present portion contains descriptions of the species of only five out of the thirteen families into which the author divides the group. W. S. D.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

The Teachings of Tribulation—"The Captain"

THE technical questions suggested by the loss of Her Majesty's ship *Captain* have received their full share of attention—indeed, more than their share, for able leaders and letters in the newspapers will not teach us how to build war ships. I do not intend to trouble you with freeboards, turrets, and metacentres. Nor do I propose to dive into all the published evidence and statements, in order to discover some delinquent on whom to saddle the blame of the terrible disaster.

The case of the *Captain* is an example, on a scale sufficiently startling to attract the notice of the whole nation, of a want in our administrative arrangements which has hitherto escaped the notice of the many. The few who have long deplored this want did not require that a quarter of a million of money and 500 gallant lives should be sacrificed in order to prove its existence. Employing, then, the loss of the *Captain* as merely one very striking instance out of thousands of others that pass unheeded every day, permit me to suggest what is the administrative lesson taught by it. The facts must first be briefly stated. This cannot be better done than by quoting a portion of the judgment of the court-martial, who tell us that they "find it their duty to record the conviction they entertain that the *Captain* was built in deference to public opinion as expressed in Parliament and through other channels, in opposition to the views and opinions of the Controller of the Navy and his department, and that the evidence all tends [*sic* in *Times*' report] that the Controller of the Navy and his department generally disapproved her construction."

Now let us analyse the system the working of which justified the above reiterated condemnation. Beginning at the top, we have a Minister of State, a gentleman usually of high character and great general attainments, but not necessarily conversant with naval architecture. Being a party politician, he may at any moment vacate his post on some question totally unconnected with his department. In order to provide him with the knowledge which he does not pretend to possess, and to supply the element of permanence in which he is also deficient, he has under him secretaries, superintendents of works, and scientific advisers. These persons are in the strictest sense of the terms also subordinates of the Minister, bound to obey his orders. Outside this department are two bodies, independent of the Minister, and capable of bringing enormous pressure to bear upon him, namely, inventors and the public—the first interested, the second ignorant of science and owing no responsibility to any one. I disclaim any personal allusions in this analysis. Well, here we have two forces pulling the Minister different ways. The whole question is, whether the departmental, or, as we may call it, the home, force is strong enough to enable the Minister to resist, when necessary, the foreign invader; whether reiterated adjurations, noisy clamour, and threatened loss of popularity will silence and overbear official counsels. The question is already answered. The official counsels were overborne. It may be argued, however, that the official counsels may be wrong and the public right. But the official counsels in the case before us were right and the public wrong. Here we are landed in a difficulty. How is the Minister, who by our hypothesis has no knowledge of the question at issue, to tell when his advisers are right and when the public? He cannot tell. But he exercises his discretion. Now, it must be remembered that his advisers are his subordinates, and therefore, taking men as we find them on an average, not in a position calculated to prompt them to oppose very strenuously a policy on which they see that their superior is set. Moreover, the advisers, who in the case before us are but two or three individuals, may be, as it was believed they were, prejudiced against the contrivance under consideration. It would be natural that the Minister should make a considerable deduction from the weight of their remonstrances on account of the departmental jealousy by which he might imagine them to be more or less tinctured. Thus he is at sea, as deficient in the elements of stability as the *Captain* herself.

An obvious remedy for such a state of things might be to appoint as permanent heads to our great technical departments men thoroughly acquainted with their duties who could act on their own independent judgment. But this would subvert that perfect and inviolable edifice, the British Constitution. Far be it from a humble unit like myself to attempt such sacrilege!

What remains, then, as we cannot repress inventors and silence public clamour if we would, than to give the Minister stronger and more independent scientific support than that which was found in the case of the *Captain* too weak to prevent the most humiliating and disastrous blunder of modern times?

The suggestion I now venture to make is not new, nor do I make it now, on the pinch of the moment, for the first time. I brought it more than a year ago before a committee of the British Association, of which I was chairman. My proposal was, and is, that a powerful body of the most eminent men in every branch of science should be constituted a permanent paid Council for consultative, as distinguished from executive, purposes. Space does not admit of my detailing the constitution, mode of electing, and functions of this body. But, having long had the matter in my mind, I may say that I see no difficulty in securing the main conditions of varied and profound acquirements, and of due official relation to, yet thorough independence of, the Ministry and politics of the day. I need hardly say that such a consultative Council should comprise not only men distinguished in abstract science, but also men representing all branches of the sea and land forces, all technical departments, the public works, and the principal arts and manufactures of the country.

No mistake can be greater than to consider this proposal revolutionary, as some at first sight have done. It is in fact only a consolidation and systematisation of agencies actually in existence. The principle of supplying the country gentlemen who become Ministers of State with scientific advice through permanent secretaries and other subordinates, and through temporary committees entrusted with specific inquiries, has long been in force. It is certain that these individuals and bodies are often selected capriciously, and it is not saying too much to assert that the results of their labours would have been more valuable if their functions had been less narrow and their existence less precarious. The great domain of physical science cannot be parcelled out in neat little squares like a chess-board; its varied districts, as Nature has planned them, run into and mix with each other so intimately that in order to trace the boundaries of one, some knowledge at least of the adjoining tracts is necessary. Special committees, however well chosen, are seldom even numerically strong enough to comply with these conditions.

The Council now advocated purposes to substitute for innumerable, scattered, temporary, incomplete, hand-to-mouth expedients a permanent, properly selected organisation. In one case the work is done somehow—we see to our cost how; in the other it will be done as well as human intelligence can do it; but in both cases the very same work will be done—namely, that of bearing really the burden of responsibility which Ministers only bear nominally. The principle will be the same under the existing and the proposed régime, but whereas it is now only recognised, it would then be realised. The details of the proposed reform, which are present to my own mind, would occupy more space than you could spare on one occasion from other important subjects. Nor is it possible in the brief limits of one letter to meet all those objections, now so well known to me, which start up directly this subject is mooted. Should, however, the remarks I have ventured to offer prove of sufficient interest to provoke discussion, I will on a future occasion solicit your permission to extend them.—I am, Sir, obediently yours,

Oct. 22 ALEX. STRANGE, Lieut.-Colonel

The Earliest Mention of the Aurora Borealis

THE first appearance of the Aurora Borealis noticed in Mr. E. J. Lowe's "Natural Phenomena and Chronology of the Seasons" is that on Jan. 30, 1560. Other appearances are mentioned under the years 1564, 1574, and 1575. No further record of it appears until Nov. 10, 1707, when it was seen in Ireland. Five more displays are noticed between this and the memorable one of Feb. 23, 1716, which, happening to take place on the day of Lord Derwentwater's execution, obtained for the phenomenon in the north of England the appellation of "Lord Derwentwater's Lights." On March 6 of the same year occurred another grand display, which is referred to in the chronologies of remarkable occurrences published in the almanacks of last century as "The Great Amazing Light in the North," continuing to be seen (more or less) at several times since, yearly. Previous displays in this century had probably not been visible in London. The phenomenon is thus described, with an attempt at explanation, in the *Flying Post* of March 8:—

"Last Tuesday night, as soon as it was dark, a pale sort of a light broke out in the north-west part of our horizon, which looked like the dawn of day, or rather like the moon breaking through the clouds. It darted many streams towards all parts of the sky, which looked like smoke. It proceeded towards the S.E., and continued by several intervals till midnight, when it totally disappeared. Some ignorant people, whose ideas are on such occasions stronger than their senses, fancied they saw armies engaged, giants with flaming swords, fiery comets, dragons, and the like dreadful figures; and others fancied they heard the report of fire-arms, and smelt powder; whereas there was nothing but what may easily be accounted for from natural causes, the sun having been hot for two days past, and particularly that afternoon, by which vapours were exhaled both from the earth and water, and the sulphurous particles mixed with them taking fire might occasion that light, and some coruscations, as is very common over marshy and fenny places in spring and summer nights."

The writer goes on to observe that "the disaffected party have worked this up to a prodigy, and interpret it to favour their cause," which accounts for a very obvious design to write the phenomenon down. Another display, not in Mr. Lowe's list, was witnessed at Leominster, on Feb. 21, 1718, as appears by a letter in the *Weekly Journal* of March 1. The streamers are there compared to the tail of the great comet of 1681.

London, Nov. 7 R. G.

THE fallacy of trusting for scientific information to any other than a recognised scientific source, cannot be better illustrated than by Mr. Pocklington's letter in your issue of Nov. 3. He there seems to thinks that the statements of the editor of a volume of popular poems on a matter of science are worthy of notice, and therefore thinks it worth while to inquire whether or not it is true that no aurora borealis ever appeared before 1715. The absurdity of such a rash statement is so apparent that it seems almost superfluous to show it. In 1754 a book was published by M. de Mairan, entitled, "Traité Physique et Historique de l'Aurore Boréale," in which he collects from all the writers, ancient and modern up to that date, accounts of all the Auroræ Boreales which had been seen. Their total number amounts to 1,441 between the years A.D. 583 and 1751.

These are divided as follows: From A.D. 583 to 1354, 26 were recorded; 1354 to 1560, 34; 1560 to 1592, 69; 1592 to 1633, 70; 1633 to 1684, 34; 1684 to 1721, 219; 1721 to 1745, 961; 1745 to 1751, 28. Of these, 972 occurred in the winter half year, and 469 in the summer half year, the greatest numbers occurring in March and October. Since that date the two most remarkable displays have been those of the 23rd of October, 1804, and the 24th of October, 1847. An account of the latter aurora was published at Cambridge in the same year, giving twelve large coloured lithographic views of the brilliant display which are, without doubt, the best views ever given of any Aurora.

J. P. EARWAKER

Merton College, Oxford, Nov. 5

THE quotation given by C. Pocklington in your last issue as the words of the Editor of Routledge's edition of Collins's Poems, is the very note given by Dr. Langhorne in the "Poetical Works of William Collins," published in the year 1808, in a small book entitled "The Laurel," and as it has not been reprinted word for word its sense is somewhat obscured. In the original it runs thus:—

"By 'Young Aurora' Collins undoubtedly *meant* the first appearance of the Northern Lights, which happened about the year 1715, at least it is *most* highly probable, from *this* peculiar circumstance, that no ancient writer *whatever has* taken any notice of them, nor even any *one* modern, previous to the above *period*."

The words restored are those italicised. The passage, as it came from Dr. Langhorne, is excusable for the knowledge displayed, but cut up as it is by the *modern* editor, shows great lack of it; and more than this, the honesty is not what every one would admire. Both, however, are incorrect. Dr. Halley, in the Phil. Trans., No. 347, page 406, gives a history of auroral observations, and for the information of "C. P." I have extracted a few particulars showing that the "northern lights have been observed and recorded long before 1715.

The first account, says Dr. Halley, recorded in English annals is that of the appearance which was noticed January 30, 1560, and called "Burning Spears," by the author of a book entitled "A Description of Meteors," by W. F., D.D. London: 1654. The next of a like kind was the appearance recorded by Stow, which occurred on October 7, 1564.

In 1574, Camden and Stow inform us, an Aurora Borealis was seen for *two* successive nights, viz., the 14th and 15th of November, with appearances similar to those observed in 1716, and which are not commonly noticed. The same phenomenon was twice seen in Brabant in 1575, viz., on the 13th of February and the 28th of September, and the circumstances attending it were described by Cornelius Gemma, who compares them to spears, fortified cities, and armies fighting in the air. In the year 1580, M. Mastline observed these *phasmata*, as he calls them, at Baknang, in the county of Wurtemburg, in Germany, no less than seven times in the space of twelve months; and again at several different times in 1581. On September 2, 1621, the same phenomenon was seen all over France; and it was particularly described by Gassendus in his "Physics," who gave it the name of "Aurora Borealis." Another was seen all over Germany in November 1623, and was described by Kepler. Since that time, for more than eighty years we have no account of any such phenomenon either at home or abroad. In 1707 Mr. Neve observed one of small continuance in Ireland. In the years 1707 and 1708 this sort of light had been seen no less than *five* times.

There is not the least doubt in my mind that the commentator of Collins must have been wholly ignorant of the literature of scientific records, else he would never have said what he did on the lines in question.

In the Orkneys the Northern Lights are known by the name of the "merry dancers." And it is not at all surprising among an unphilosophical people, that this, one of the grandest phenomena in nature, should be the subject on which the imagination fondly dwells.

The various conflicts of Odin may probably have been suggested by the dancing and flickerings of these Lights.

In the "Prosa Edda" there is a direct allusion to the Aurora Borealis; at least, the translation given in Mallett's "Northern Antiquities," edited by J. A. Blackwell (1847), page 404. It says:—"From his skull," continued Thridi, "they formed the Heavens, which they placed over the earth, and set a dwarf at the corner of each of the four quarters. These dwarfs are called East, West, North, and South. They afterwards took the wandering sparks and red hot flakes that had been cast out of Muspellheim, and placed them in the Heavens, both above and below, to give light unto the world, and assigned to every *other errant coruscation* a prescribed locality and motion."

If by "errant coruscation" he meant all the meteoric phenomena including the Northern Lights, then we have in this "Edda" the most ancient record of this observation.

Hereditary Deformities

THE following instance of hereditary deformity is taken from Mr. L. W. Dillwyn's "Materials for a Fauna and Flora of Swansea and the Neighbourhood" (Swansea, 1848), a privately printed and therefore little known book. It will be seen that the evidence respecting the origin of the malformation is not conclusive: "In 1804 there was in the Neath Valley a remarkable breed of a sort of sheep-dog, with nothing more than a flat depression, about half an inch broad, between the nostrils, and was said to have originated in a bitch which had her nose longitudinally cloven by some accident. The breed retained this deformity for several years, but I believe it is now extinct."

The same book contains the following very remarkable illustration of the dispersion of species by means of oceanic currents: "On the sandy sea-shore, opposite the race-course on Crumlyn Burrows, and more than a mile from any sort of house or garden, Mr. L. L. Dillwyn, in 1839, found a thriving young plant of *Yucca gloriosa*, and it had all the appearance of having risen from a seed which the tide had cast there. Notwithstanding its exposed situation, and the looseness of the soil, this native of Carolina was not materially injured by the unusually severe winter of 1840-1, and Mr. Moggridge informs me that for two or three years it continued to thrive, till it was destroyed by a heap of shingle, which a violent storm and high tide threw over it."

Fertilisation of Plants

WITH candle in hand I have pored through all that you have printed of the speeches delivered by the members of the British Association at Liverpool, till I made a full stop at page 482, where I found "Observations on Protandry and Protogyny in British Plants, by A. W. Bennett, F.L.S.—The arrangement of the reproductive organs in hermaphrodite plants, the presence in the same flower of both pistil and stamens, suggested to the minds of the older botanists no other idea than that of self-fertilisation. It is, however, now generally admitted that even in hermaphrodite flowers, cross-fertilisation is the rule, self-fertilisation the exception. Two sets of facts have been especially observed—in particular by Darwin in this country, Hildebrand in Germany, and Delpino in Italy—to favour cross-fertilisation in hermaphrodite flowers, the phenomena of dimorphism and trimorphism, and the special arrangements which render it easier for the pollen to be brushed off by insects visiting the flowers than to fall on its own stigma." I cannot understand what this special arrangement which renders it easier for the pollen to be brushed off by insects visiting the flowers, can mean, when applied to the flowers of our forced peaches, French beans, &c., in blossom during the dark months of December, January, February, and March, when there is no insect on the wing.

As I do not keep bees in my garden, and there are none kept within a mile of it, and if there should a swarm of bees take up an abode near us, I destroy it, my peaches blossom and set their fruit without the assistance of the bee or any other insect. It is the sun that sets the blossoms, so to speak, and consequently we make the best use of every gleam of sunshine that by chance may visit the earth during the blooming time of our forced "things."

From this fact it must be evident that the Creator did not leave the all-important functions of the fertilisation of flowers to the insects which are simply in search of food, though it amuses our great thinking and closely observing philosophers to try to assure us plodding practicals of our sheer ignorance in the *modus operandi* of the fertilisation of hermaphrodite flowers.

That insects disperse the pollen of flowers there cannot be a doubt. Neither is there a doubt that hermaphrodite flowers fertilise their own pistils during the dark months of winter, without the presence of plundering insects. An industrious morphologist might find much employment in an early forced peach-house, in flower, say in January, on which the sun may not have gleamed since the first blossom opened.

A PEACH-GROWER

[Our correspondent should read the article in NATURE, No. 1, by Mr. Bennett, "On the Fertilisation of Winter Flowering Plants," which he will find to be in accordance with his own views.—*Ed.*]

Chip Hats

IN the last number of NATURE it is stated that palm-leaf was formerly imported to St. Alban's for the purpose of making *chip* hats. Allow me to state that the trade has never ceased. Large quantities of palm-leaf are imported under the name of "Brazilian grass," and many persons are constantly employed in St. Alban's and the villages around in plaiting these hats, principally for exportation. They are called *grass* hats.

Kew, Nov. 16 F. H. HOOKER

The Electric Telegraph and Earthquakes

THE use of the electric telegraph for recording earthquakes is not so new as the *Echo* (quoted in your last number, p. 35) supposes. Dr. Hector, Director of the Geological Survey, has, ever since the last great convulsion, systematically used the telegraph for this purpose in New Zealand, where indeed it forms an important element in the admirable system he has inaugurated for recording shocks throughout the islands. In his last letter he writes as follows:—"Not long ago, one operator asked another 200 miles distant 'Did you feel that?' and got the answer, 'No. What? Yes; there it is,' all in a breath, so to speak!"

Dr. Hector, writing in August last, goes on to say, "I have called attention to the coincidence of the aurora in both hemispheres on April 5, and can't help thinking that when our observations are sufficiently extended, we shall find many phenomena that are looked upon as local to be general. Could not NATURE give us a column recording such phenomena as auroras, earthquakes, tornados, &c., experienced in all parts of the world, somewhat in the form of an almanac? At the present one has to rummage over all sorts of periodicals, and after all find the matter most imperfectly recorded. We shall soon have a capital earthquake register here, since I induced the Government to cause the observers to report every shock they felt in the colony. Their number and coincidence is very remarkable, and I shall publish the results as soon as I have collected a sufficient number. I feel a great want of a good table eusmometer which should be cheap enough to distribute to all telegraph stations." Perhaps some of your readers can inform Dr. Hector where he can procure this great desideratum. JOS. D. HOOKER

Ocean Currents

AMONG the "Notes" in last week's number it is mentioned, on the authority of the *Inverness Courier*, that a number of glass globes had lately been washed ashore on the western coast of the Isle of Lewis. The question is asked, "Have these been used for some experiments made for the purpose of ascertaining the course of some ocean current?" I have seen precisely similar globes which had been cast ashore after rough weather on the western coast of Shetland; and I ascertained that they were floats used by Norwegian fishermen for buoying their long lines. North-easterly winds had drifted them to that part of the coast where they were found; and the same cause may be assigned for the occurrence of the glass globes or floats in the outer Hebrides. J. GWYN JEFFREYS

Nov. 12

IN reference to the statement (NATURE, Nov. 10) that glass globes have been washed ashore on the west side of the Isle of Lewis, may not these be floats which are used by the fishermen of Newfoundland? These are, I believe, occasionally found as far to the north-east as Nova Zembla, and this fact is, I think, not indicative of "some ocean current," but of the *aerial* current from the south-west, which is so prevalent in the north temperate region, and which may be called the *return* current of the north-east trade wind of the north tropical region.

This south-west wind from the sea modifies the summer heat and the winter cold of west coasts in the north hemisphere, and produces their so-called "insular climate."

GEORGE GREENWOOD, Col.

Brookwood Park, Alresford, Nov. 12

The Milky Way

THERE appears to be in Wales a remnant of a tradition connected with the Milky Way. During a short stay in Caermarthenshire, an old man, well read in local history, and who is apparently the oracle of the neighbourhood of Llangadock, directed my attention one evening to the Milky Way, remarking at the time "we shall have fair weather to-morrow, as you see it is in the south," meaning that the wind will blow from that quarter. My friend supported this extraordinary statement by appealing to the Welsh word "Heol y Gwynt," the *road or way of the wind*. Can any of your readers inform me whether this belt of stars is the subject of a fable in Britain, or how it came to be connected with foretelling the weather? The Scandinavians call it the "Road of Winter;" possibly "Heol y Gwynt" may be traced to northern influence, but, in the absence of facts, I will not commit myself to this explanation.

JOHN JEREMIAH

43, Red Lion Street, Clerkenwell, Nov. 12

P.S.—"Heol y Gwynt" is the only proper Welsh name for the Milky Way, and is not a mere local one.

The Colour of Butterflies' Wings

IN making some experiments a short time ago, I came across a fact of which I was hitherto ignorant. I wished to test the effect of acid on the colours of the wings of a butterfly or moth, and with this view applied muriatic acid to a dried and set specimen of the Six-spotted Burnet (*Zygæna filipendulæ*). The red parts immediately became yellow, while the dark parts were unaltered. In subsequent experiments the red was the only colour in any moth which underwent any change. When there was no red there was no change, and the only change was from red to yellow. Next I applied the acid to the red parts of the Red Admiral Butterfly (*Vanessa atalanta*), when, to my surprise, no change took place. Comparative examination under the microscope in no way cleared up the matter. I now seek for an explanation of this phenomenon, which appears to point out a clear difference in the nature of the moth and butterfly's wing. A remarkable fact, perhaps connected with this, is that a yellow variety is known of almost every moth containing red in the wings. Perhaps some of your scientific readers may be able to throw some light upon this subject. E. V. F.

Winchester, Oct. 18

A New Mode of Evolving Light

A SINGULAR phenomenon of the evolution of light has been recently observed by me. By tearing sharply a piece of twilled calico into strips in a room well guarded from light, a perceptible luminosity was clearly distinguishable, which appeared at its maximum at the final parting of the fabric. This phenomenon is exceedingly well marked in dry, new calico, and appears to me due to the dressing, as after being washed no light is evolved. Whether attributable to electricity, phosphorescence, or fluorescence, I leave for further investigation. The light appears similar to that produced on breaking a lump of sugar in the dark. So far as I can ascertain, the phenomenon of light being evolved on tearing a fabric is new, hence I hope worthy of notice in your valuable journal. ANDREW PRITCHARD

Canonbury, N.

Philology and Darwinism

IN NATURE, No. 30, I attempted to show that the analogy between Mr. Darwin's teachings as regards plants and animals, and the conclusions of comparative philologists, broke down, when we compared man's conscious influence on plants, &c., to his more and more enlightened control of language. Man's influence on organic forms tends to produce variety, while, with increase of knowledge, language is becoming more uniform. Mr. Ransom (No. 32) replied that the difference I insisted on seemed imaginary; and if man's object was to produce uniformity in plants or animals, that then the domesticated species would be likely to become less varied than the wild species of the family. Now it seems to me that if man had any such intention, no care on his part could produce permanent types yielding so little divergence in the individuals during enormous time as those produced by nature; a permanence so marked that geology only throws light on the law of evolution, in anything like a direct way, through the study of the mammalia (see Prof. Huxley's recent address on the progress of Palæontology), and even with regard to the mammalia naturalists of high standing refuse to see anything but permanent and all but uniform types, necessitating the hypothesis of special creation. How man could obtain by any possible efforts (and with some breeds his aim is uniformity) to maintain species as invariable as nature has done, is what is hard to conceive.

On the other hand, as man's mental faculties become blunter, his consciousness less vivid, and his material conditions harder, his language is more and more in a state of flux, branching forth continually into dialects which mark one group of men from another. Thus in some Polynesian islands we have a number of languages as distinct as those of great part of Europe; and missionaries complain that the Bible requires to be translated anew to the same tribe more than once in a century; in some cases the very numerals in a few generations becoming changed, partly from whimsical customs, and partly from want of frequent intercourse, and of any literature being at the disposal of the tribe. In the progress of time, we may look forward to a period when the language of Shakespeare, Milton, and Addison, which is considered as good English as that of our daily papers—may be the language of the world, but we can scarcely expect that the planet will ever hold only one species of animal or plant. S. J.

NATURAL SELECTION—MR. WALLACE'S REPLY TO MR. BENNETT

MR. A. W. BENNETT'S article entitled "The Theory of Natural Selection from a Mathematical Point of View," contains several criticisms on my own writings, and touches on some points which have not yet been fully discussed. I propose, therefore, to reply to such of these as appear to be of sufficient importance.

The first objection brought forward (and which had been already advanced by the Duke of Argyll) is, that the very title of Mr. Darwin's celebrated work is a misnomer, and that the real "origin of species" is that spontaneous tendency to variation which has not yet been accounted for. Mr. Bennett further remarks, that throughout my volume of "Essays" I appear to be unconscious that the theory I advocate does not go to the root of the matter; and this unconsciousness is not apparent only, for I maintain, and am prepared to prove, that the theory, if true, does go to the root of the question of the origin of species. The objection, which, from its being so often quoted and now again brought forward, is evidently thought to be an important one, is founded on a misapprehension of the right meaning of words. It ignores the fact that the word "species" denotes something more than "variety" or "individual." A species is an organic form which, for periods of great and indefinite length as compared with the duration of human life, fluctuates only within narrow limits. But the "spontaneous tendency to variation" is altogether antagonistic to such comparative stability, and would, if unchecked, entirely destroy all "species." Abolish, if possible, selection and survival of the fittest, so that every spontaneous variation should survive in equal proportion with all others, and the result must inevitably be an endless variety of *unstable forms*, no one of which would answer to what we mean by the word "species." No other cause but selection, has yet been discovered capable of perpetuating and giving stability to some forms and causing the disappearance of hosts of others, and therefore Mr. Darwin's book, if there is any truth in it at all, has a logical claim to its title. It shows how "species," or stable forms, are produced out of unstable spontaneous variations; which is certainly to trace their "origin." The distinction of "species" and "individual" is equally important. A horse or a number of horses, as such, do not constitute a species. It is the comparative *permanence* of the form as distinguished from the ass, quagga, zebra, tapir, camel, &c., that makes them one. Were there a mass of intermediate forms connecting all these animals by fine gradations, and hardly a dozen individuals alike—as would probably be the case had selection not acted—there might be a few horses, but there would be no such thing as a species of horse. That could only be produced by some power capable of eliminating intermediate forms as they arise, and preserving all of the true horse type, and such a power was first shown to exist by Mr. Darwin. The origin of varieties and of individuals is one thing, the origin of species another.

Mr. Bennett next discusses the phenomena of "mimicry," and proposes to show, by mathematical calculations, that the effects could not be produced by natural selection. But, at the very outset, he makes an important error, which seriously affects his subsequent reasonings; for he leads his readers to understand that there is only one completely mimicking species of *Leptalis*, while the majority are of the normal white-butterfly type. The fact is, however, that but few species of *Leptalis* retain the simple colouring of their allies the Pieridæ, while the great majority are either coloured like the Heliconidæ, or show a considerable amount of colour or marking in that direction. He is also apparently unaware that some Heliconidæ (*Ithomia eurimediæ*, for example) approximate in colour to the normal white and yellow species of *Leptalis*, and thus renders it much less difficult to understand how a sufficient amount of variation in colour might occur at a first step, to produce a resemblance which, viewed at some considerable distance, would be deceptive, and therefore useful.

We next come to the demonstration by means of figures, and we here find still more serious errors. Mr. Bennett says, that supposing a *Leptalis* may vary in twenty different ways, one only being the direction required,—"the chance of any individual producing a descendant which will take its place in the succeeding generation varying in the required direction, is $\frac{1}{20}$; the chance of this operation being repeated in the second generation is $\frac{1}{20^2} = \frac{1}{400}$; the chance of this occurring for ten successive generations is $\frac{1}{20^{10}}$, or about one in ten billions;" whence it is concluded that there are overwhelming chances against any progressive variation in the right direction ever taking place. But first, I do not admit the assumption that only one variation out of twenty would be in the right direction; when it is remembered how great is the variety of the Heliconidæ, both in colour and marking. It seems more likely that one-fourth or one-third at least would help to approximate to some of them, and thus be useful. Taking, however, Mr. Bennett's own figures, there are three great oversights in this one short sentence. The first is, that each *Leptalis* produces, not one only, but perhaps twenty or fifty offspring; the second is, that the right variation has, by the hypothesis, a greater chance of surviving than the rest; and the third, that at each succeeding generation the influence of heredity becomes more and more powerful, causing the chance of the right variation being reproduced to become greater and greater.

Now with these three modifications the weight of the argument is entirely destroyed; for, allowing the *Leptalis* to produce only twenty offspring (a small number for a butterfly), the chances become even that one out of the twenty varies in the right direction. But nineteen out of the twenty, on the average, are soon killed off by the various causes that keep down the population of the species, and the chances are very much in favour of that one surviving which, by the hypothesis, has varied in the right direction. It is not pretended that this one would survive always, or even on the average, but in a large number of cases it would certainly do so; and taking Mr. Bennett's own estimate of a million individuals as the population of a rare species, we may fairly estimate that in a quarter, or say even in a tenth part of these, the surviving offspring would possess the favourable variation. But now a new factor enters into the problem, of which Mr. Bennett takes no account. Those that have already varied tend to leave offspring varying in the same direction as themselves; and as these will all have an advantage, the offspring of the one-tenth will increase at the expense of those of the nine-tenths; and this tendency being still more powerful in the third generation, with the additional advantage as the numbers increase of the chance of both parents being favourable varieties, we may fairly expect the favourable to have completely exterminated the unfavourable variations, and to have firmly established themselves as a well-marked race. The enormous possible rapidity of multiplication, enabling a pair of individuals to produce millions in a few generations; the survival of the fittest, giving to favourable variations—not their bare numerical chance, as Mr. Bennett supposes, but—a certainty in the long run of living at the expense of the rest; and the powerful influence of heredity, which actually increases the *tendency* to produce the favourable variations with each succeeding generation,—are three of the main foundation-stones of the theory of natural selection, yet all three are ignored in this attempted mathematical demonstration of its insufficiency.

There is one other point in the theory of the origin of "mimicry" that deserves notice. It is, that the modifications leading to it are much more easy to explain than those leading to new genera and families, because the changes effected are wholly superficial and are almost entirely confined to colour. Now colour is both more variable than any other character, and is less intimately correlated with structure, so that great changes of colour may rapidly occur without in any other way affecting the individual, as we see in almost all our domestic animals. Experiments in breeding show that very large spontaneous variations of colour are frequent in insects; and thus the number of steps to produce a required amount of change may be much fewer than in cases of structural modification, in which every other part of the organism has to be co-ordinated to work harmoniously with the modified organ.

I may here take the opportunity of denying that I have argued, as Mr. Bennett says I have, that "an infinitesimal and inappreciable distinction may make the difference of a slightly longer span of life being allowed to the butterfly to lay its eggs in safety;" and I cannot imagine how he could have imputed to me anything so absurd. What I have maintained is, that for natural selection to act, either in producing "mimicry," or structural changes, no large or special variations are required, because the usual amount of *variability* which occurs in every part of every organism is sufficient. ("Contributions," pp. 287—291.) But so far from supposing this to be "infinitesimal" or "inappreciable," I show that it is so palpable and so readily appreciated by horticulturists and breeders as to have enabled them to produce all the wonderful variety in our domestic animals and cultivated plants. And every entomologist knows that similar variability exists in insects, and that the constantly occurring variations of colour are especially great.

Mr. Bennett next returns to the laws of variation, and, because Mr. Darwin says that we are profoundly ignorant of these (although he himself has done so much to elucidate them), maintains that we cannot really know anything of the origin of species. As well might it be said that, because we are ignorant of the laws by which metals are produced and trees developed, we cannot know anything of the origin of steamships and railways. Spontaneous "variations" are but the materials out of which "species" are formed, and we do not require to know how the former are produced in order to learn the origin of the latter. But though we may not know the laws which determine each variation in detail, the general causes which lead to variation are not difficult to perceive. We do not know all the laws and causes that have given their peculiar form to each mountain or each valley, but we know a good deal of the general causes which have produced them, and we can perceive that the reason no two are exactly alike is, the number and complexity of the causes and the endless variety of conditions under which these causes have acted. In the far more complex operations of the development and growth of organisms, affected as we know they are by almost infinitely numerous and ever varying external and internal causes, it would be a much greater mystery if there were no variations, and if absolutely identical forms were produced by constant diversity of conditions. Even the successive offspring of the same parents are developed under very different conditions. At each succeeding year, and at every different period of each year, the parents have changed in age, in size, in vigour, health, and constitution; they may be living in a different locality, have different food, and be subjected to very different physical and mental influences. Add to this the effect of cross unions of distinct individuals, each with its own characteristic peculiarities, which are in varying degrees transmitted to the offspring; and further, that these modified offspring are submitted to a somewhat different set of conditions from the parents, and intercross perhaps with a distinct set of individuals; and then add the effects of atavism in bringing up long lost ancestral characters, and it can hardly be said that the almost universal fact of "spontaneous variation" is quite unaccounted for. But, as I have already remarked, this variability could never by itself produce *species*, but must absolutely prevent their production without the eliminating, accumulating, and fixing powers of selection, multiplication, and heredity.

In Mr. Bennett's concluding passages he advances a theory of his own on the subject of "mimicry," to the effect that it is connected with intelligence or instinct, "and runs almost *pari passu* with the development of the nervous system." In support of this view he asserts that it is "strongly developed in birds." This is erroneous. In birds it is very rare, only two or three cases being known, and these not nearly so remarkable as hundreds that occur in insects; and in mammalia, with the exception of one doubtful case, it is absolutely unknown. This view, therefore, is directly opposed by the facts.

I have only one more point to notice, a charge of inconsistency against myself. Mr. Bennett quotes me to the effect that man's chief peculiarities of form and structure were developed before his intellect had raised him above the condition of the brutes, and also *imputes* to me the belief that certain peculiarities in his structure (the absence of hair on his body, for example) "must have been in some way connected with *his* reasoning powers." But this is Dr. Laycock's view, which I have expressly repudiated, and I have never used a word to show that I believed that man has modified his own structure in any important degree, by the conscious or unconscious exercise of his reasoning powers. I have, it is true, declared my belief that "some intelligence" has acted on him, but I have also, I think, made it quite clear that I did not believe it to be his own intelligence. The inconsistency, therefore, is of Mr. Bennett's making.

I think I have now noticed the chief points in this last assault on the theory of Natural Selection, which has failed, like all preceding ones. Its author also exhibits the usual inability to keep steadily before him the great fundamental principles of the theory he is discussing, so that his arguments continually break down owing to his taking a partial and wholly inadequate view of its mode of operation. In the case of "mimicry" he is not sufficiently careful in his statement of the facts, and this, combined with his imperfect grasp of the theory, entirely neutralises the elaborate numerical proofs which at first sight appear so overwhelming. ALFRED R. WALLACE

SCIENCE IN PARIS

IN the course of an article on the present condition of Paris, the *Engineer* gives the following account of the effects of the war. The use of the electric light is common to both sides in the present struggle, but the French have used it largely. The apparatus set up on Montmartre is arranged by M. Bazin, and is electro-magnetic. The central cylinder supports four series of double coils covered with copper wire enveloped in silk; the cylinder is rotated by a small steam-engine of 3-horse power, making 400 revolutions per minute. The lamp used is of the ordinary form, with the Foucault-Dubosc regulator. The reflector is parabolic in form, and the whole is surrounded by a shield to hide it from the enemy. This light, from its elevated position, commands the whole of Paris and the plains around. A spectator on Montmartre sees distinctly the details of the *façade* of a building which stands 2,600 metres off; at 2,900 metres a man may be seen standing at a window, at 3,000 metres a mass of cavalry or infantry is distinguishable, and at 4,000 metres the dome of the Invalides, with its bands of gold, is brilliant. A man cannot be seen on the dome at that distance, but on walking towards the building all soon becomes clear. On the ramparts, at 3,800 metres from Montmartre, the light is sufficient to read an ordinary newspaper.

Thus, though the practical effect of the lamp only extends about 300 metres from its position, the field is illuminated to the extent of 700 metres, for the benefit of all placed between the light and the object. Thus a sentinel on the ramparts can see about 3,000 metres from the *enceinte*, and by this means strict watch is kept upon the plains around the city at night, as far, in one direction, as 1,000 metres beyond St. Denis. M. Bazin is now occupied in applying his apparatus to the purposes of night telegraphs, by the adoption of the system of flashes—mentioned some time since in the *Engineer*—and with the aid of coloured lenses. A corvette—the *Coligny*—already possesses such a signal apparatus, and the signals are distinctly visible at more than eight miles' distance. The action of the lamp, and also the movements of the apparatus, are remarkably steady, and M Bazin has received high testimonials from the authorities of the good working of his instrument.

M. Viollet-le-Duc, who is M. Alphand's second in command of the corps of civil engineers and architects aiding the military authorities, has made an interesting report to General Trochu respecting the works executed during the past month by the auxiliary engineers around Paris. It appears, according to this document, that the expense of these works has been only 105,000f., while under the military system they would have cost 230,000f. We have not seen the report, but we presume that M. Viollet-le-Duc, and the other architects and engineers, gave their services and advice gratis, and this would, of course, save the country a considerable sum.

The Government has voted the sum of 40,000 francs to enable M. Dupuy de Lôme to carry out his proposed plan of navigable balloons. The subject has been twice discussed in the Academy of Sciences, and although some members have advocated the use of a small steam-engine or other motive power, M. Dupuy de Lôme is no doubt wise in adhering to manual power, which presents all the force necessary with none of the inconveniences of machinery, and an adaptability to circumstances which no machinery can possibly possess. The men will form a crew to aid the landing of the balloon, or in extricating it from any difficulty, while any engine would be, when not in use, a dead weight and awkward encumbrance. Moreover an aërostat, with steam or other power, is now in construction by another inventor or adapter.

During the discussion M. Dupuy de Lôme showed by calculations that his balloon would have a constant ascensional force up to 870 metres altitude, but beyond that to 1,110 metres a little gas must be lost. At all events, between 250 metres and 870 metres the altitude could oscillate (by means of the extra pocket or swimming bladder) without loss of gas; and, of course, there would be the usual expedient of ballast to be depended on also. Dr. Monra advocated the use of heated air in place of gas. Fifty deg. Centigrade would be sufficient, and the heat might be retained by making the balloon double—that is to say, one balloon within another. The Aigle Mongolfière, said the Doctor, used to be inflated in twenty minutes, while it takes a whole day to fill a balloon (upwards of 1000 cubic metres) with gas. Mongolfier balloons sent up within twenty leagues of Paris would certainly fall in the city, and it is a pity they have not been tried before this. Should the siege not soon be raised, will not the English aëronauts or others try and send a few letters into Paris?

PROFESSOR HELMHOLTZ ON FARADAY

WE have been favoured by Prof. Tyndall with the following translation of a portion of the preface to the German Edition of "Faraday as a Discoverer," recently superintended by Professor Helmholtz:—

"The name of Faraday is one to be held in reverence by all natural philosophers. Many times in London, in connection with lectures which I delivered at the Royal Institution, I had myself the privilege of his obliging help and the pleasure of his amiable society. The perfect simplicity, modesty, and undimmed purity of his character gave to him a fascination which I have never experienced in any other man. I had therefore a duty of gratitude to fulfil towards him.

"But apart from this, and apart from that friendship for Faraday's younger associate and successor, the author of this book, which induced me to undertake the task, I believed that I should render a service to German readers by facilitating, as far as in me lay, an insight into the action and character of a mind so richly and peculiarly endowed, and so entirely the product of natural growth.

"It is, moreover, by no means for the philosopher only that such an insight possesses interest. His interest, certainly, is the most immediate, for it has hardly been the lot of any single man to make a series of discoveries so great and so pregnant with the weightiest consequences as those of Faraday. Most of them burst upon the world as surprises, the products, apparently, of an inconceivable instinct; and Faraday himself, even subsequently, was hardly able to describe in clear terms the intellectual combinations which led to them. These discoveries, moreover, were all of a kind calculated to influence in the profoundest manner our notions of the nature of Force. In the presence of Faraday's magneto-electric and diamagnetic discoveries more particularly, it was impossible for the old notions of forces acting at a distance to maintain themselves, without submitting to essential expansions and alterations. The clearer expression of these changes is at the present hour the object of physical science.

"In what way such extraordinary results were achieved is naturally a question of the first interest to the investigator who strives after similar though more modest ends. But Faraday's development appears to me to possess no small human interest in relation to many theoretic questions of psychology, and to the art of education. The external conditions under which he cultivated those striking capacities which excite our wonder were the simplest that can be imagined. He was completely self-taught; brought up in humble circumstances, having received no more than the commonest instruction, and having been only favoured by fortune in the circumstance, that when he was a poor apprentice to a bookbinder, he found, at the right time, a helper in Humphry Davy, who recognised his peculiar gifts, and procured for him the possibility, though in a subordinate position, of working in the direction towards which his genius impelled him.

"And throughout his whole life and labours, the advantages and disadvantages of such a mode of development reveal themselves in simpler and larger traits than in the case of most other similar celebrated names. The principal advantage rose undoubtedly from the fact that his intellect was not too soon subjected to theoretic fetters, but enjoyed its freedom in the presence of natural phenomena; and that instead of book-learning he permitted the fulness of Nature herself to operate upon his open mind. The disadvantages are, perhaps, of a subordinate kind; but they reveal themselves in quite as unmistakeable a manner when he strives to give expression to his ideas; and to supply, by all kinds of sensuous imagery, the want of mathematical culture. This is manifestly the way in which he alighted upon his Lines of Force, his Ray Vibrations, and other notions, which bewildered the investigators of his time, and the truer and clearer meaning of which has been in part made out by mathematical theory since Faraday himself ceased from his labours.

"And still, in this unlearned son of a smith, who held fast throughout his life the pious creed of his fathers, ran a vein of philosophy which gave him the right to be ranked among the foremost of those engaged in the general intellectual travail of our age. That as Tyndall informs us, he retained the term "Natural Philosophy," usual in England to express physical science, and the name "Philosopher" for the cultivator of that science—lies essentially in the nature of his work. After the science of our age, in its laudable efforts to make human knowledge a true image of the actual universe, had shattered many an old metaphysical idol, it halted amid the transmitted forms of physical ideas regarding Matter, Force, Atoms, and Imponderables. These names were even converted into new metaphysical shibboleths by those who thought themselves most advanced in the way of enlightenment. It was these ideas that Faraday sought in his riper labours to purify from everything theoretical, which was not the true and immediate expression of the facts. More especially he opposed the action of forces at a distance, the assumption of two electric fluids and of two magnetic fluids, and, in like manner, all hypotheses which contradicted the law of the conservation of force, of which he had an early presage, though he singularly misapprehended its mathematical expression. And in these precise directions he exercised, in the first place, the most unmistakeable influence on the physicists of England. The mathematicians among them, especially, labour to render theories of phenomena the pure and true expression of the laws of fact, to the exclusion of all arbitrary theoretic devices. In this way Faraday's ideas, though in a modified form, often reveal themselves with their true significance assigned to them."

EARTHQUAKE OF OCTOBER 20, 1870

WE have been favoured with the following particulars of this earthquake by Prof. Newton, of Cambridge, U.S.A.:—

On Thursday morning, Oct. 20, an earthquake vibration was felt throughout Canada, and the northern part of the United States from Maine to Iowa. It seems to have been more severe in Canada and in New England. In many places the shock was sufficient to throw down chimneys, crack the walls of buildings, and do other damage. It was remarkably severe for the region of country visited. At New Haven, as well as in many other places, there were two distinct series of vibrations. Prof. Twining has carefully collected information from several persons as to the time of the occurrence and duration of the vibrations. The beginning of the first shock was at $11^h\ 19^m\ 45^s$ A.M. New Haven mean time. It lasted ten seconds, and its individual vibrations were about two-thirds of a second in duration, or one and one-third second for a complete double vibration. After an interval of five seconds there was a second series like the first lasting eleven seconds. The motion was not a simple oscillation, but there was a rocking motion, indicating a vertical component in the movement of the earth. The vibrations were not severe enough to arrest universal attention, though multitudes felt a peculiar sensation without recognising the cause. The direction of the vibration was N.N.E. to S.S.E. At Cambridge, Mass., according to Prof. Winlock, the direction was about 10° north of east, as determined by the appearance of the sides of a vessel containing milk. Mr. Farmer, at Boston, gives $11^h\ 25^m\ 37^s$ for the time of the ending of the vibrations, Cambridge mean time. This would imply that the shock reached Boston a minute and three-fourths earlier than New Haven. At Cleveland, Ohio, several clocks were stopped by the earthquake, each indicating very nearly $10^h\ 45^m$ A.M. This is approximately the instant at which the shock reached New Haven. It is reported that the shock reached Quebec 30 seconds before it did Montreal, the telegraph operator of the former city being in the act of inquiring of the operator in the latter one respecting the earthquake, when it arrived at Montreal. These data seem to show that the general progress of the wave was from North to South. Slight vibrations were felt as far south as Richmond, Va., and as far west as Dubuque, Iowa.

NOVEMBER METEORS OBSERVED AT THE RADCLIFFE OBSERVATORY

THE following is a list of Meteors observed at this Observatory by Mr. Lucas, on the nights of November 12, 13, and 14, 1870.

On Nov. 12 a watch was kept from $7^h\ 15^m$ to $8^h\ 30^m$, and from 11^h to $13^h\ 30^m$.

At $8^h\ 20^m$ a meteor was seen of the 4th magnitude, from Capella, a little to northward.

At $12^h\ 29^m$, one of the 1st magnitude, white, flashed from α Cephei to α Cygni.

At $12^h\ 48^m$, one of the 1st magnitude, from α Ursæ Majoris to Polaris, below the stratus cloud which overspread the sky, and nearly hid all the stars, the two mentioned being just visible. Duration, $1^s{\cdot}5$.

At $12^h\ 57^m$, one of the 1st magnitude, white, seen for an instant about 7° or 8° east of Polaris, appearing to burst over the point of appearance; motion southwards.

Nov. 13.—At $8^h\ 5^m$, one of the 3rd magnitude, visible for 3^s, downwards towards the south.

At $8^h\ 20^m$, one of the 1st magnitude, visible for 2^s, with a long train, from ϵ Cygni to α Aquilæ.

At $9^h\ 38^m$, brighter than Jupiter, of a blue colour, visible for 4^s, from near Capella to o Ursæ Majoris.

The sky was overcast at $11^h\ 30^m$, and continued so nearly all the night, raining from 14^m to 16^m.

Nov. 14.—At $10^h\ 54^m$, one of the 1st magnitude, white, visible for $1^s{\cdot}5$. From β Aurigæ to a cloud near 25 Lynxis; direction, N.E.

At $11^h\ 1^m$, one of the 1st magnitude, visible for $1^s{\cdot}5$. From a cloud a little to the west of Rigal; downwards.

At $11^h\ 19^m$, one of the 1st magnitude, visible for 2^s; near ι and χ Andromedæ to α Cygni.

At $12^h\ 33^m$, one of the 4th magnitude. From α Cephei downwards; a short path.

Cloudy from 10^h to $11^h\ 30^m$; tolerably fine afterwards till 13, when clouds covered the sky again.

ROBERT MAIN

NOTES

WE are glad to announce that the Government has expressed its intention to aid in the most ample manner the proposed Eclipse Expeditions. In making this announcement we feel that what has recently appeared in the daily Press renders certain explanations desirable, which otherwise might have been omitted. In our last number we stated that deputations had been appointed both by the Joint Committee and the Council of the British Association to wait upon Mr. Gladstone. To this we must now add that the letter of the Secretary of the Joint Committee, which was to ask Mr. Gladstone to appoint a time to reeeive a deputation, was not sent to Mr. Gladstone, and did not ask that a time should be named; in fact it was a letter sent to the *Treasury*, apparently only for their information, and was nothing more than a copy of the resolution passed at the meeting of the Joint Committee. After a week had elapsed without any answer being received by the Joint Committee to the letter which it was supposed had been sent to Mr. Gladstone, asking him to name a time for a deputation; a member of the Joint Committee, Mr. Lockyer, called at the Treasury to inquire the reason of the delay in the answer, and of course he was informed that no letter had been received requiring any answer. Upon it being represented that a delay in the announcement of the Government intentions until a proper letter could be received from the Secretary of the Royal Society would be fatal to the Expedition, Mr. Lockyer was requested to state the actual requirements of the Scientific Bodies to Mr. Lowe, and upon his having done so, the Chancellor of the Exchequer, who, so far as we know, heard then of the expedition for the first time, at once expressed his opinion that such an expedition was one eminently worthy of Government aid, and that the Government would do all that was requisite to further the objects sought. This decision of the Government was announced to the Royal Astronomical Society by the Astronomer Royal on Friday last, and since then, the arrangements for the Expedition have moved apace. There will be a ship furnished by the Government to carry observers to Spain. There will be funds to convey observers overland to Naples, and a ship to carry them on to Messina. The various European governments have been requested to aid the various parties, and, generally, the influence of the Government is being brought to bear in every way. This taken in connection with what has appeared in these columns before, and a letter which the Astronomer Royal has addressed to the *Daily News*, shows that now all the facts are out, the whole blame of the long delay must fall on the officers of the Joint Committee, who, apparently unable to perform the duties entrusted to them, still did not call the Committee together to receive instructions We should not write in so decided a tone on such a painful subject did we not feel that it is simply an act of justice to the Government to state, as plainly as our information enables us to do, exactly where the real blame rests.

IT will have been observed that Dr. Carpenter's letter in our number for Oct. 27, called in question, on the authority of Sir R. I. Murchison, the accuracy of our report of the conversation which followed the reading of Mr. Gwyn Jeffreys' paper in Section C of the British Association. We have communicated, in consequence, with Mr. Jeffreys, by whom we were favoured with the report in question, and who assures us that "to the best of his recollection and belief the report was quite accurate as conveying the purport of Sir Roderick Murchison's remark." While, therefore, we are unable to decide the relative accuracy of two different recollections of the same circumstance, we cannot but congratulate ourselves that the misunderstanding, if it were so, has drawn out such a full exposition of Dr. Carpenter's views of the bearings of the *Porcupine* discoveries on modern geological and physico-geographical theories.

IN addition to the notices of papers to be read at the meetings of the scientific societies in London, we shall be glad to insert in our "Diary" the titles of those to be read at the leading provincial societies, when of sufficient interest, and if forwarded to us in good time.

BRASENOSE College, Oxford, offers an open fellowship for Natural Science or Mathematics in February next. Candidates for Natural Science must communicate with the Principal by letter not later than the 20th December. As this is one of the few colleges which have hitherto held entirely aloof from Natural Science, this fellowship is clear evidence that the value of such studies is yearly becoming more appreciated at Oxford.

THERE will be offered for competition, at St. John's College, Cambridge, in 1871, an Exhibition of 50*l*. per annum for proficiency in Natural Science, the Exhibition to be tenable for three years in case the Exhibitioner have passed within two years the previous examination as required for candidates for honours: otherwise the Exhibition to cease at the end of two years. The candidates will be examined in (1) Chemistry, including practical work in the laboratory: (2) Physics, viz., electricity, heat, light; (3) Physiology. They will also have the opportunity of being examined in one or more of the following subjects—(4) Geology, (5) Anatomy, (6) Botany, provided that they give notice of the subjects in which they wish to be examined four weeks prior to the examination. No candidate will be examined in more than three of these six subjects, whereof one at least must be chosen from the former group. It is the wish of the masters and seniors that excellence in some single department should be specially regarded by the candidates. They may also, if they think fit, offer themselves for examination in any of the classical or mathematical subjects. The Exhibitions are not limited in respect to the age of candidates. The examination will take place on April 21st and 22nd, and the names of candidates must be sent in at least ten days beforehand.

THE series of science lectures addressed to working men at Manchester are a great success. Three weeks ago Prof. Huxley opened the series by a very interesting lecture on Coral Islands. On Wednesday se'nnight, Prof. Roscoe lectured on Spectrum Analysis, and this week Mr. Huggins lectured on the Spectrum Analysis of the Stars. These lectures, which are to be continued through the winter, have been literally crowded by most attentive audiences, and since full reports are published in the Manchester daily papers, there is every hope that much permanent benefit will be derived from them.

THE following are the lecture arrangements at the Royal Institution of Great Britain for 1870-71:—Christmas lectures (adapted to a juvenile auditory), Prof. Odling—Six lectures "On Burning and Unburning," on Dec. 27, 29, 31, 1870; Jan. 3, 5, 7, 1871. Before Easter, 1871, Prof. Michael Foster—Eleven lectures "On the Nutrition of Animals," on Tuesdays, Jan. 17 to March 28; Prof. Odling—Eleven lectures "On Davy's Discoveries in Chemistry," on Thursdays, Jan. 19 to March 30: Mr. W. H. Channing—Four lectures "On the Progress of Civilisation," on Saturdays, Jan. 21 to Feb. 11; Prof. Jowett—Three lectures "On Socrates," on Saturdays, Feb. 18, 25, and March 4; Mr. H. O'Neil—Four lectures "On the Spirit of the Age," on Saturdays, March 11 to April 1. The Friday evening meetings will commence on Jan. 20. The Friday evening discourses before Easter will probably be given by Profs. Tyndall and Odling, the Dean of Westminster, Mr. E. J. Reed, Mr. James W. Douglas, Dr. Carpenter, Capt. Noble, Prof. Clerk Maxwell, Mr. Norman Lockyer, and Mr. W. Mattieu Williams. After Easter:—Prof. J. J. Sylvester—Three lectures "On Emanuel Kant," on Tuesdays, April 18, 25, and May 2. Mr. Charles Brooke—Two lectures "On Force and Energy," on Tuesdays, May 9 and 16. Prof. Tyndall—Eight lectures, on Thursdays, April 20 to June 8. Mr. Norman Lockyer—Eight lectures "On Astronomy," on Saturdays, April 22 to June 10.

THE *British Medical Journal* reports that at a meeting of a committee held in Edinburgh on November 7, it was stated that the form of the national memorial to the late Sir James Y. Simpson had been agreed upon as follows: 1. A monument and statue in Edinburgh; 2. A marble bust in Westminster Abbey; 3. A hospital in Edinburgh for the diseases of women, constructed on those principles which Sir James so often and so clearly enforced; 4. Similar hospitals in London and Dublin, should sufficient funds be obtained. It was also stated that a sum of 1,950*l*. had already been subscribed.

AFTER the conclusion of the ordinary business of the meeting of the Royal Medical and Chirurgical Society on Tuesday the 8th inst., the meeting was made special for the purpose of confirming, or rejecting, the following resolution, proposed by Mr. Paget, seconded by Dr. Quain, and passed at a special meeting of the Society on October 25th:—"That the Council be requested to consider whether, while maintaining the charter and constitution of the Royal Medical and Chirurgical Society, it may be possible to obtain a more complete co-operation with the Pathological, Obstetrical, Clinical, and Epidemiological, or other societies for the promotion of Medical Science." After a lengthened debate, Dr. Paget's resolution was confirmed by a small majority.

THE *Chemical News* gives a short account of a convenient form of spectroscope for use in a laboratory, by Mr. John Browning. It is so constructed that it may be kept in close proximity to a chemical laboratory without injury. The prism is provided with a cover, which should be put on with a little bees'-wax; or, better still, bees'-wax and tallow. This prism, with cover complete, can be removed, and replaced without deranging the adjustment of the instrument, to allow of a bottle prism being substituted for the purpose of taking the refractive index or dispersive power of any liquid. The stand of the instrument is of wood, and the whole is enclosed in a circular cover which fits tightly round the base of the instrument, and has no other joint or opening.

THE Leeds Naturalists' Field Club will hold the following conversational open meetings, at the Rooms, South Parade, every alternate Monday evening, at eight o'clock:—(1870), November 7, "A November Day at Boston Spa," Mr. J. W. Taylor; November 21, "Geology as a Study," Mr. L. Acomb; December 5, "Life History of the Painted Lady Butterfly (*Vanessa Cardui*)," Mr. W. Turner; December 19, "Animalculæ," Mr. W. Coates; (1871), January 2, "The History of a Mushroom," Mr. J. Abbot; January 16, "Wasps," Mr. W. D. Roebuck; January 30, "Our Trees and their Uses," Mr. Jas. Brodie; February 13, "Protozoa," Mr. T. Hick, B.A.

THE Annual Exhibition of the Photographic Society of London was opened at the Architects' Gallery, No. 9, Conduit Street, by a private reception of their friends by the members of the Society, and the exhibition will remain open to the public until the last day of the current month of November. The exhibition is quite as large as was the eminently successful exhibition of last year, and certainly leaves the impression that there is manifest and unmistakeable evidence of progress in the art during the year. The work of many of the leading and best known exhibitors is in advance of their exhibited specimens of the last year, and there are some individual photographs now to be seen upon the walls of the gallery which it can hardly be too much to say are of higher excellence, both as pictures and as photographs, than any that have before been produced. We may mention in particular ten large portraits by Col. Stuart Wortley, taken direct from life, and marvellous specimens of tasteful and exquisite portraiture; two large portraits, also from life, by Mr. Warwick Brookes, of scarcely inferior power and excellence; Vandyke and Brown's solar camera enlargements of the poet Longfellow; and Mr. Blanchard's large Rembrandtesque life portraits. Of large landscape work, Mr. Care, of Worcester, deserves special notice; and Mr. Robinson's sea pieces, "Turn of the Tide" and "Outward Bound," are admirable bits of true nature. Mr. Robert Faulkner has some very pretty applications of the instantaneous branch of the art in catching the fitful aspects and characteristics of children; and Mr. Vernon Heath has two exquisite bits of true scenery and foliage; nor ought we to pass by "Hop-picking," by Mr. Stephen Thompson, and Captain Lyons' Indian pictures; and we may add to this list Mr. Manners Gordon's small pictures from dry plates.

HERR A. PETERMANN has published a brief paper, in which he recapitulates the main results of the various North Pole Expeditions of the present year. Herr von Heuglin and Count Zeil, of the German Expedition, remained from July 15 till Sept. 15 in and near East Spitzbergen, which they explored, mostly in boats, from 77° to 79° N. lat. They claim to have discovered extensive land to the east of Spitzbergen. This land, Herr Petermann maintains, it is a mistake to identify with the land discovered by Gillis in 1707, which lay 80° N. lat. The land which was seen from the White Mountain of Spitzbergen by the Swedish Expedition in 1864, 80 nautical miles to the east, was put down on the map as a neck of land lying 79° N. lat. "Herr von Heuglin and Count Zeil," says Herr Petermann, "have now discovered, 36 nautical miles to the east of Spitzbergen, a continent, extending from 79° to 78° N. lat.—therefore, from north to south, at least 60 (German) miles—which contains numerous sharply-pointed peaks, and which, in case it is really connected with Gillis Land, might at least equal Spitzbergen in size." This is claimed as the most important polar discovery that has been made for some years. Herr Heuglin has brought home with him from East Spitzbergen fourteen chests of geological, zoological, and botanical specimens. The news of the war reached the explorers in September. Count Zeil, a lieutenant in the Second Royal Würtemberg Jäger Battalion, at once hastened home to Stuttgart, and, having had an audience of the King on October 20, proceeded forthwith to his regiment in France. Herr Petermann announces that the Russian Expedition, which has been accompanied by the famous academician, Von Middendorff, has prosecuted interesting scientific researches between Novaia Zemlia and Iceland. Among other things, it is said, he has identified the Gulf-Stream as far as Novaia Zemlia at the very considerable temperature of + 10° Réaumur. With reference to an article by Herr Petermann on the subject of the Gulf-Stream, Herr von Middendorff writes to him:—"I am extremely glad that your theory respecting the extension of the Gulf-Stream is not only confirmed, but has even been greatly surpassed; you were bold, but Mother Nature is still bolder."

AT a time when so much is being said about the value of fungi in general as profitable and wholesome articles of food, and also when France is being so largely overrun by foreign troops, the following notes on the Truffle cultivation in the Department of the Dordogne, written a short time before the outbreak of the present war, may be of some interest. It shows the money value of these delicacies, and how profitable a business is their cultivation. The method adopted for propagating them is to sow acorns, and the best truffles are found under the resulting oak-trees; but the evergreen oak, and juniper trees are also grown for the same purpose. An instance is cited of a person who inherited a piece of land worth 8*l.*, and who thus sowed it with acorns; the truffles thereby obtained realise now as much as 160*l.* a year. There are many varieties easily distinguishable to those accustomed to the trade. The truffle is dearer in Périgord than in Paris, where it is mixed with an inferior quality, and therefore can be sold at a lower price. It comes to perfection about the middle of November, but large quantities are collected and sent to market in September and October. These are called "fleurs," and are without smell. It is pretended that they have not come to maturity, and that a large portion of the produce is thus spoilt. The total revenue derived from the truffle commerce amounts to 20,000*l.* a year in the Arrondissement of Tarlat, and to about the same amount in Périgueux.

IT is interesting to note the progress the Japanese are making in the art of printing, &c. Hitherto they have only been acquainted with the Chinese mode of printing, from engraved wooden blocks. Lately, however, they have engaged the services of an English gentleman, to set up for them an establishment for type-founding, electrotyping, and printing on the Western method, and to give them such instructions in these arts as will enable them afterwards to carry on the business. Type-founding and electrotyping have now for the first time been introduced into Japan.

AT the last ordinary meeting of the Hackney Scientific Association, held on Nov. 8th, Mr. Henry T. Vivian announced that he had discovered the variability of ϵ Herculis, a small star to the N.E. of π. From observations extending back to the autumn of last year, he had deduced a period of about 21 days, with probably a second longer period. The amount of variability in the star's lustre is from a large 5th mag. to a small 6th. The star is numbered 60 in Map 10 of Mr. Proctor's New Star Atlas, although in Map 8 it is numbered 69; evidently an error on the part of the engraver.

THE MICROSCOPE

THE VALUE OF NITRATE OF SILVER AS A REAGENT FOR DEMONSTRATING MINUTE STRUCTURE.—Since Von Recklinghausen drew attention to the beautiful results to be obtained by the use of a weak solution of nitrate of silver, in the study of the finer distribution of vessels, and especially of the lymphatics, much discussion has taken place as to the trustworthiness of results obtained by this method, and there are some histologists of merit who maintain that the whole thing is false and delusive in its effect. The method consists in immersing perfectly fresh (warm from the animal) tissues in a ½ per cent. aqueous solution of nitrate of silver, leaving them there for from five to ten minutes, and then, after thorough washing, mounting in glycerine, and exposing to sunlight for half an hour, or two or three hours as the case may be. If desired, the tissue may be plunged while fresh into serum (preserved with just a trace of iodine), and after two hours' maceration therein may be smoothed with a small paint-brush, to remove superficial epithelium (as, for instance, in the centrum tendineum of the guinea-pig), and then placed in the silver solution. It is, however, preferred by Dr. Klein, of Vienna, to brush away the superficial epithelium of the thoracic surface, if the lymphatics of the centrum tendineum are to be examined, before removing the diaphragm from the body, whilst perfectly fresh and warm, warm water being used for this purpose, and a camel's-hair paint-brush: immediately after this "pencilling" the centrum tendineum is cut out and placed in the nitrate of silver solution. In the same way, in researches on the cornea the conjunctival epithelium may be removed in the living animal and the silver solution then applied. Dr. Klein, Professor Stricker's assistant, has found that the best results were to be obtained with the cornea, by removing the conjunctival epithelium, and rubbing the corneal surface well with lunar caustic, and removing the cornea in half an hour's time. This method proves admirable with frogs, and is probably applicable to other corneæ. The results of the nitrate-of-silver-staining as seen in the centrum tendineum, are that both thoracic and peritoneal epithelium (where not pencilled away) are stained, the outlines of the cells being brought out very distinctly. In addition to this the epithelium lining the vessels which run in the centrum is also brought out, and especially the curiously crenated epithelium of the fine lymphatics is demonstrated. Moreover, Recklinghausen pointed out that small branched cavities become delineated connected by their branches to one another, and opening into the lymphatics with the crenate epithelium. These lacunar channels, "the juice canals," are brought into view by the action of the silver in staining the substance of their walls but leaving the cavity free. A *successful* silver preparation of the centrum tendineum of a guinea-pig, for instance, shows these structures clearly, but it is not always possible to succeed. Besides the remarkable epithelium of the lymphatics and the juice-canals, a hexagonal pavement of enormous cells is demonstrated on the nerve sheaths, and an exceedingly fine cell pavement on the adventitia of the small veins in some beautiful silver preparations of the "centrum" made by Dr. Burdon Sanderson. The results in the cornea are very remarkable, for the whole substance of that tissue in the frog is demonstrated to be filled with oblong radiating cavities, communicating with one another by their branches, and of so angular and regular a character as to give the appearance of a mosaic-work or some such elaborate device. These cavities correspond to the juice-canals in the centrum tendineum, it is by their means that the cornea is nourished, it is they which contain the large star-like cells or protoplasm-masses brought out by gold chloride, and it is along their branches that the divided portions of these cells wander so remarkably in the process of inflammation. And now we are told by some persons that these are artificial productions, that the juice-canals and the radiate lacunæ, and the crenate lymphatic epithelium too, are due to fortuitous coagulation caused by the silver, that they do not represent structures existing in life. There are two sets of objectionists, some who deny the whole thing, others who go so far as to deny the juice-canals and stellate lacunæ, but admit the epithelium. An exponent of the first order is a certain Dr. Robinski, who in a paper published in the excellent *Archives de Physiologie* of Brown-Séquard, pretends that the crenate epithelium which so many have seen in the finer lymph vessels, as well as the juice-canals, are due to imperfect retention of portions of the superficial epithelium, and gives a drawing intended to show this. The author of the paper has simply failed utterly and entirely in using the method, and the outrageous view which he advances does not require refutation. Everyone knows who has made silver preparations successfully that the thoracic, the lymph-canal, and the peritoneal epithelium may all be seen lying one over the other in parts of a preparation, and that the form of the second prevents its being mistaken for the first or third. Others maintain that the crenate lymph-epithelium is simply a form due to the silver, and not to cells at all. This is impossible, because the nucleus and cell-contents are sometimes clearly demonstrated, and moreover the same form of epithelium may be readily obtained from large lymph-sacs, of some of which it is characteristic. The juice-canals, if they appear doubtful at all when taken by themselves (which indeed they do not if a *good* preparation is examined), when seen in the light of the stellate lacunæ of the frog's cornea, are clearly understood, and must be fully admitted as normal living structures. There are, however, persons who object to these, among whom is so eminent a histologist as Professor Schweigger-Seidel, and also that accomplished micrographer, Dr. Ranvier, of Paris. They actually hold that these forms are *post-mortem* products, the effect of the action of nitrate of silver on the albumen and gelatine of the tissue. It is almost as strong a position to take up as that of certain schoolmen who maintained that we know nothing of the anatomy of living animals, since the air admitted on cutting them open, and the scissors, produced all the various viscera seen in a dissection. There are some strong facts which we have witnessed which render such a view untenable. In the first place, the stellate lacunæ of the frog's cornea are shown in a preparation in our possession, with the intermediate substance stained by *gold* and the lacunæ and cells unstained, in fact, exactly the same appearance as is produced with silver. Hence the stellate form of the lacunæ cannot be due to a specific action of the silver. Again, by silvering the living cornea whilst it is still part of the frog, the structure is brought out, and may be obtained of all degrees of intensity, the *form*, however, always remaining the same, and not varying with the amount of silver allowed to act on it, as might be expected had we to do with a precipitation-form, which should appear less completely developed when less silver is used. Moreover, the living cells were thus demonstrated lying in these stellate lacunæ, creeping up the radiating branches, drawing back again, and creeping along others, thus obtaining that curious direction to their movements which one always observes in studying them in the fresh, unstained, inflamed cornea. The necessity of admitting that the normal structure of the frog's cornea is brought out by the silver method, covers also the question as to the similar structures in the centrum tendineum. The "Saft-canälchen" must equally be admitted as having a living existence, and are not due to the imaginary precipitating action of nitrate of silver on some albuminoid, as Schweigger-Seidel would have us believe, but a parallel to which he cannot find. The chief difficulty with regard to the crenate epithelium of the lymph vessels in the centrum tendineum is to explain why we only see one layer of these cells; they should appear all round the wall of the vessel so as to produce a double layer as we look through it, but we only see one layer, the other not being stained. The action of light, the absorption of the silver, and other causes, may be hazarded as explanations of this; but it would be satisfactory to get a double layer clearly shown.

So far, then, from agreeing with Schweigger-Seidel and other objectors, that the silver method of Von Recklinghausen "gives no true indication of the structure of the cornea," nor of similar structures, and "should be abandoned,"* we believe that when carefully applied it furnishes most admirable results, difficult to attain in any other way at present in our hands, and is worthy of all confidence, and should be used as a means of investigation in other structures besides those to which it has been already applied.

E. R. L.

REPORT OF THE KEW COMMITTEE OF THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE FOR 1869-70

THE Committee of the Kew Observatory submit to the Council of the British Association the following statement of their proceedings during the past year:—

At the meeting of the General Committee at Exeter it was re-

* Berichte der Math. Phys. Classe der Kön. Sachs. Gesellsch. 1869. p. 352.

solved that the existing relations between the Kew Committee and the British Association be referred to the Council to report thereon. In consequence of this resolution, the Kew Committee, on the 23rd November, 1869, prepared for the information of the Council a statement on the past and present condition of the Observatory, which was presented to the Council on the 11th December. In this statement it was shown that while the establishment at Kew Observatory received its main support from the British Association, and was under the control of that body, yet much of the apparatus in use at Kew was furnished from other sources. Thus, the Royal Society had from the Government-Grant Fund supplied the establishment with the apparatus for testing barometers, with that for testing sextants, with the dividing-machine for constructing standard thermometers, and also with the set of self-recording magnetographs at present in use, while from the Donation Fund they had furnished the photoheliograph and the Whitworth lathe and planing-machine. The Royal Society had likewise defrayed from the Donation Fund the expense of introducing gas into the Observatory, and of building a house for the verification of magnetic instruments, besides which they had borne from the Government-Grant Fund since 1863 the whole expense of working the Photoheliograph (including the purchase of a chronometer) and of reducing its results. The instruments used at Kew for determining the absolute magnetic elements are the property of Her Majesty's Government, and have been lent to the Kew Observatory by the Magnetic Office at Woolwich, under the direction of Sir E. Sabine, and many of those magnetic instruments with which Kew has been the means of furnishing scientific travellers have been derived from the same source. Of late Kew has become the central observatory of the Meteorological Committee, and a commodious workshop has been erected near the Observatory by that committee, since otherwise the main building would have been too small for the access of work consequent upon the arrangement entered into. The statement prepared by the Kew Committee contained likewise a summary of the scientific work done at the Observatory, as well as some interesting historical remarks connected with the origin of the establishment, drawn up by Sir C. Wheatstone, and in this shape it was submitted to the Council of the British Association. The Council then recommended "That the present existing relations between the Kew Observatory and the British Association be continued unaltered until the completion, in 1872, of the magnetical and solar decennial period, and that after that date all connection between them should cease." In consequence of this recommendation, the Kew Committee were led to contemplate the dissolution of the Kew establishment in 1872, and they became anxious to make such arrangements as might enable them to complete their scientific labours in a creditable manner before the time of the anticipated dissolution. The magnetic work in particular caused them anxiety; for the annual income of the establishment is insufficient to permit of that work being fully completed by the time of the annual meeting of the Association in 1872. Under these circumstances the chairman offered to supplement the deficiency. It will be seen by this report that the magnetical tabulations and reductions are now proceeding very fast. The recommendation of the Council was also a matter of anxiety to the superintendent, Mr. Stewart; and as the Professorship of Natural Philosophy at Owens College, Manchester, became vacant about this time, he applied for the appointment and was successful in obtaining it. This will render it necessary for Mr. Stewart to reside in Manchester, but the staff at the Observatory are such that Mr. Stewart will undertake by their aid to assist the committee in the superintendence of the work of the Observatory until 1872.

(A) Work done by Kew Observatory under the direction of the British Association.

1. *Magnetic Work.*—In the present state of magnetical science it would appear to be desirable to preserve as completely as possible the details of observations, so that future theorists may have a large and valuable source of information by which to test their speculations. The Committee are therefore desirous that by the autumn of 1872 a manuscript record should be completed, containing all the hourly tabulated values from the Kew Magnetographs arranged in monthly tables. This record should be carefully preserved, along with the original photographic traces, in the archives of the Association. Pursuing the method indicated by Sir E. Sabine, and adopting the separating values finally determined by him, the Committee further propose to obtain monthly results indicating the following points for each of the three magnetic elements, distributed according to the hour of the day:—

1. Aggregate of disturbance tending to increase the numerical values.
2. Aggregate of disturbance tending to decrease the same.
3. Solar-diurnal range of the undisturbed observations.

They suggest that the monthly results embodying these facts should be published in detail. Finally, they propose to continue the discussion of the lunar-diurnal variations commenced by Sir E. Sabine, and carried on by him up to the end of the year 1864. In order to work this scheme with sufficient rapidity to complete it before the autumn of 1872, additional assistance has been procured, the expense of which has been defrayed by the chairman. Mr. Whipple, magnetical assistant, has displayed much zeal and ability in organising the work and in superintending its immediate execution. Already the hourly numerical values of the three magnetic elements have been obtained and tabulated in monthly forms from the commencement of the series in 1858 to the present date; and considerable progress has also been made in the next step of the reduction. A unifilar, formerly employed by Captain Haig, and of which the constants have been determined at the Observatory, has been lent to Lieut. Elagin, of the Russian navy, for use in the Japanese seas and elsewhere. A dip-circle, by Dover, has been verified and sent to Prof. Jelinek, of Vienna, and another, by the same maker, has been verified for Dr. A. B. Meyer, for use in the East Indies. This gentleman has likewise received magnetic instruction at the Observatory. A dip-circle by Adie, furnished with a deflecting cylinder apparatus, has been verified and despatched to Prof. Bolzani, of the University of Kasan. Three dipping-needles have likewise been constructed for Dr. Bergsma, of Batavia, and one for Mr. Chambers, of the Colaba Observatory, Bombay. A deflection-bar has been procured and verified for the Russian Central Observatory. A declinometer has been sent to the Lisbon Observatory, and a Fox's circle has been lent to Dr. Neumayer, after having been repaired by Adie. The instrument devised by Mr. Broun for the purpose of estimating the magnetic dip by means of soft iron, and constructed at the expense of the British Association in pursuance of a resolution of that body passed at the Oxford meeting, has been forwarded to that gentleman at his request. The usual monthly absolute determinations of the magnetic elements continue to be made by Mr. Whipple, magnetic assistant. A paper embodying the results of the absolute observations of dip and horizontal force, made at Kew from April 1863 to April 1869, has been communicated by the superintendent to the Royal Society, and published in the "Proceedings" of that body. The results obtained evidence the accuracy with which the monthly observations have been made by Mr. Whipple. The self-recording magnetographs are in constant operation as heretofore, also under his charge; and the photographic department connected with these instruments remains under the charge of Mr. Page.

2. *Meteorological work.*—The meteorological work of the Observatory continues in the charge of Mr. Baker. Since the Exeter meeting, 150 barometers have been verified, and thirty have been rejected; 1,160 thermometers and 103 hydrometers have likewise been verified. Nineteen standard thermometers have been constructed for Prof. Tait, and two for the Meteorological Office. The self-recording meteorological instruments now in work at Kew will be again mentioned in the second division of this report. These are in the charge of Mr. Baker, the photography being superintended by Mr. Page.

3. *Photoheliograph.*—The Kew heliograph, in charge of Mr. Warren De la Rue, continues to be worked in a satisfactory manner. During the past year 351 pictures have been taken on 237 days. It was considered desirable that six prints should be obtained from each of the negatives of the sun pictures taken at the Observatory during the whole time that the photoheliograph should remain at work, which will probably be from February 1862 to February 1872. In order to accomplish this, an outlay of 120*l.* spread over two years was found to be necessary, and this sum has been voted from the Donation Fund of the Royal Society. A large number of these prints has already been obtained, and it is proposed to present complete sets to the following institutions:—

The Royal Astronomical Society,
The Imperial Academy of Paris,
The Imperial Academy of St. Petersburg,
The Royal Society of Berlin,
The Smithsonian Institution, United States,

leaving one set for the Royal Society. A paper embodying the positions and areas of the sun-groups observed at Kew during the years 1864, 1865, and 1866, as well as fortnightly values of the spotted solar area from 1832 to 1868, has been communicated to the Royal Society by Messrs. Warren De La Rue, Stewart, and Loewy. This paper is in course of publication in the "Philosophical Transactions," and will shortly be distributed. A table exhibiting the number of sun-spots recorded at Kew during the year 1869, after the manner of Hofrath Schwabe, has been communicated to the Astronomical Society, and published in their monthly notices. M. Otto Struve, director of the Imperial Observatory at Pulkowa, visited England in the month of August last. He brought with him, for the Kew Observatory, some sun-pictures made at Wilna with the photoheliograph, which, it will be recollected was made some yearsago, under the direction of Mr. De La Rue, by Mr. Dallmeyer. This instrument combines several important improvements on the original Kew model, the value of which is forcibly brought out in the superior definition of the Wilna sun-pictures. As, however, the series of the ten-yearly record at Kew was commenced with the instrument as originally constructed, it was not deemed desirable to alter it in any way until the series had been completed and reduced, and the corrections for optical distortion ascertained and applied. In the event of the sun-work being continued after 1872, it will be desirable to do so with a new and improved heliograph. M. O. Struve proposed to exchange the complete series of pictures obtained at Wilna for that made at Kew. He also stated that it is contemplated to erect a second heliograph at the Central Observatory at Pulkowa.

4. *Miscellaneous Work.*—A few experiments have been made on the rotation of a disc *in vacuo.* By an arrangement devised by Mr. Beckley, a very perfect carbonic-acid vacuum has been obtained, the residual pressure being 0·02 inch as indicated by a mercurial gauge with a contracted tube, but it was believed that the vacuum was even more perfect. A disc of paper and one of ebonite gave very sensible heat effects in such a vacuum, and it was hoped that the experiments might have been satisfactorily completed; but while they were in progress the pressure of the outer atmosphere shattered the receiver into a number of pieces, fortunately without any injury to the experimenters. Another receiver has now been made, and it is purposed in future to use it with a cover. A transit instrument has been lent to Mr. G. J. Symons, and one sextant has been verified.

(B) WORK DONE AT KEW AS THE CENTRAL OBSERVATORY OF THE METEOROLOGICAL COMMITTEE.

It is stated in the report for 1867 that the Meteorological Committee had appointed Mr. Balfour Stewart as their secretary, on the understanding that he should, with the concurrence of the Kew Committee, retain his office of Superintendent of the Kew Observatory. On the 8th October, 1869, Mr. Stewart resigned his appointment as Secretary to the Meteorological Committee and Director of their Central Observatory—a step which took effect on the 31st of March, 1870, and which was followed by a modification of the relation between the two committees. The Meteorological Committee, at their meeting on 12th November, 1869, resolved that they were prepared to make the following proposals to the Council of the British Association:—

I. That Kew be continued as one of the ordinary self-recording observatories, in which case the committee would be prepared to allot to it annually 250*l.*; or,

II. In addition to the foregoing work, that Kew be maintained as the central observatory for examination of records and tabulations from all the other observatories, in which case the committee will be prepared to allot a further annual sum of 400*l.* The Kew Committee, having been furnished with this resolution of the Meteorological Committee, resolved that it be recommended to the Council of the British Association that Kew be continued for the next two years as one of the ordinary self-recording observatories of the Meteorological Committee, that body allowing it annually 250*l.*; and that, in addition, it be maintained as the central observatory for the examination of the records and tabulations from all the other observatories, for the further sum of 400*l.* per annum. This arrangement was approved by the council; and it was thereupon resolved by the Kew Committee, that out of the 650*l.* received from the Meteorological Committee, 200*l.* be given to Mr. Stewart for superintending the meteorological work of the Observatory, this resolution to take effect after 31st March, 1870.

1. *Work done at Kew as one of the Observatories of the Meteorological Committee.*—The barograph, thermograph, and anemograph furnished by the Meteorological Committee are kept in constant operation. Mr. Baker is in charge of these instruments. From the first two instruments traces in duplicate are obtained, one set being sent to the Meteorological Office and one retained at Kew; as regards the anemograph, the original records are sent, while a copy by hand of these on tracing-paper is retained. The tabulations from the curves of the Kew instrument are made by Messrs. Baker, Page, and Foster.

2. *Verification of Records.*—The system of checks devised by the Kew Committee for testing the accuracy of the observations made at the different observatories continues to be followed, the only alteration being that the Kew staff, at the suggestion of the Meteorological Office, have undertaken to rule on the barograms and thermograms a set of zero lines, which are of great use in pantagraphic operations. Mr. Rigby continues to perform the main part of this work; Mr. Baker, Meteorological Assistant, having the general superintendence of the department.

3. *Occasional Assistance.*—The Meteorological Committee have availed themselves of the permission to have the occasional services of Mr. Beckley, Mechanical Assistant at Kew; and he has lately been visiting the various observatories of the Meteorological Committee. The self-recording rain-gauge mentioned in last report as having been devised by Mr. Beckley has been adopted by the Meteorological Committee, and instruments of this kind are at present being constructed for their various observatories. The staff at Kew continue to make occasional absolute hygrometrical observations by means of Regnault's instrument, with the view of testing the accuracy of the method of deducing the dew-point from the observations with the dry and wet bulb thermometers. Two erections have been made in the grounds adjoining the Observatory, and on one of these a large Robinson's anemometer is placed, while a small instrument of the same kind is placed on the other. By this means the indications of the large and those of the small-sized instrument may be compared with each other. The cost of this experiment has been defrayed by the Meteorological Committee.

J. P. GASSIOT, Chairman

Kew Observatory, Sept. 9, 1870

SCIENTIFIC SERIALS

THE November number of the *Geological Magazine* (No. 77) opens with an article by the editor, Mr. H. Woodward, on Fossil Crustacea from various formations. The species described and figured by the author are *Scyllaridia bellii* from the London clay of Sheppey, and *Palæga carteri* from the lower chalk. One of the most important papers in the number is on the coal-bearing rocks of Southern Chile by MM. Lebour and Mundle. The coal appears to be only a kind of lignite; it is found in beds of tertiary age. Mr. Lucy contributes a paper on the Post-pliocene Drift of Charnwood Forest; Mr. H. F. Hall, a note on the Glacial and Post-glacial deposits in the neighbourhood of Llandudno; Mr. L. C. Miall, a paper on the formation of swallow-holes in mountain limestone; and Mr. E. Wilson, a notice of some altered clay-beds and sections in Tideswell Dale, Derbyshire. The remainder of the number is occupied as usual by reviews, notices, and miscellaneous matter.

THE October number of the *American Naturalist* (vol. iv., No. 8) is chiefly devoted to Geological and Archæological subjects. It opens with an address on recent advances in Geology, delivered by Mr. J. H. Foster to the American Association for the Advancement of Science, and contains also a paper on the Primitive Vegetation of the Earth by Dr. J. W. Dawson, and a note on Indian Stone Implements by Mr. J. H. Gregory. The only other paper is a short note on bud-variations in the colour of the flowers in *Trillium* and *Wisteria.* This number also contains an interesting illustrated report of the nineteenth meeting of the American Association, including a valuable paper by Dr. A. S. Packard, jun., on the embryology of *Limulus polyphemus;* and another, by Prof. E. D. Cope, on the Structural Characteristics of the Cranium in the Lower Vertebrata.

Proceedings and Communications of the Essex Institute.—The first part of volume vi. was published in the spring of this year. Of four papers given in it, three relate to entomological subjects; these are descriptions (with figures) of numerous species of ants from Mexico, by Mr. Edward Norton; an excellent monograph of the Phalangea (Harvest Spiders) of the United States, by Dr. Horatio C. Wood, also illustrated; and an important notice of insects inhabiting salt water, by Dr. A.

S. Packard. The fourth paper is a continuation of Mr. A. E. Verrill's Synopsis of the Polyps and Corals collected by the American North Pacific Exploring Expedition in the years 1853 to 1856; this includes descriptions of a great many new species, and is illustrated with two plates. This part also contains the "Proceedings" of the Essex Institute for the year 1868.

The third part of the *Zeitschrift* of the German Geological Society, including its proceedings for the months of May, June, and July, opens with a long and important memoir, by M. F. J. Würtenberger, on the Tertiary Formation of the Klettgau, a district situated on the northern border of the Swiss Molasse. The tertiary deposits, which are referred by the author to the Miocene and Oligocene periods, are of both freshwater and marine origin, and appear to be very complicated; fossils are scarce in them, except in certain localities, which have furnished the remains of plants and animals in considerable abundance. Prof. Ferdinand Roemer describes and figures a new fossil *Python* from the Island of Eubœa, under the name of *P. euboicus*. The specimen is contained in a slab of tertiary calcareous marl slate, and the portion preserved indicates that the snake would have been about nine-and-a-half feet long when living. M. H. Laspeyres communicates a monographic revision of the genus *Leaia* (T. R. Jones) belonging to the Phyllopodous Crustacea. He discusses the systematic position of the genus, which he places among the Linmadiadæ, and of which he describes and figures five species, one of them (*L. wettinensis*) as new, and two others as having been previously described as varieties of *L. Leidyi*. All the other papers relate to mineralogical subjects; they include a continuation of Prof. G. vom Rath's valuable geognostico-mineralogical Italian fragments; an analytical notice of the Palatinite of Norheim, by Prof A. Kenngott; and a notice of the occurrence of zircon in the hypersthenite of the Radauthal near Harzburg, by Prof. Gustav Rose.

THE *Journal of Botany* for November contains a continuation of Dr. Seemann's Revision of the Bignoniaceæ and several articles of special interest to British botanists. There is also a reprint of an interesting paper by Dr. Parry, of Washington, read at the recent meeting of the British Association, on the North American Desert Flora, between 32° and 42° north latitude. He calls particular attention to the contrast between the annual and perennial vegetation of desert tracts, the former being very evanescent and rapid in its growth; the latter either storing up a large amount of surplus nourishment in their thick tuberous or tap roots, or, in the case of trees and shrubs, possessing exposed stems and foliage of the most scant and starved character; spine-clad branches and green-backed stems are, in many places, made to supply the office of leaves, or, where these latter are present, they are often chiefly coated with resinous varnish, or clothed with tomentose hairs or scales, serving to check evaporation.

SOCIETIES AND ACADEMIES

LONDON

Zoological Society, Nov. 1.—Prof. Newton, F.R.S., V.P., in the chair. The Secretary read a Report on the additions that had been made to the Society's Menagerie during the months of June, July, August, and September. Amongst the more valuable acquisitions, particular attention was called to a collection of animals from Chili, purchased in the month of July last. Of twenty-two species obtained in this collection, no less than twelve were new to the Society's series, and some of these, such as Burmeister's Cariama (*Chunga burmeisteri*) and the small Coscoroba Swan (*Cygnus coscoroba*) were of special interest. Another valuable addition was a male of the Ethiopian Ant-bear (*Orycteropus Æthiopicus*) from Upper Nubia, purchased July 29. This animal had been placed in company with the Cape Ant-bear (*Orycteropus capensis*) acquired in June 1869, and afforded an opportunity for the comparison of the two species together.—A communication was read from Prof. W. Peters, containing an elaborate memoir on the structure of *Pectinator spekei*, a peculiar Rodent of Eastern Africa. The specimens on which Dr. Peter's memoir was based, had been obtained by Mr. William Jesse, during his travels as Zoologist in company with the Abyssinian Expedition.—A seventh letter on the Ornithology of Buenos Ayres, addressed to the Society by Mr. W. H. Hudson, was read.—Prof. Newton exhibited a chick of *Anarhynchus frontalis*, a rare wader from New Zealand, remarkable for possessing an asymmetrical bill.—Mr. C. Darwin, F.R.S., communicated a note on the habits of the Pampas Woodpecker (*Chrysoptilus campestris*), in reply to some observations on this subject made by Mr. W. H. Hudson, in one of his previous letters.—Six communications were read from Dr. J. E. Gray, F.R.S., on various points connected with the Natural History of the Testudinata. The first of these contained notes on three Tortoises living in the Society's Gardens, one of which was believed to be new to science, and was proposed to be called *Testudo chilensis*. The second contained descriptions of two new species of Indian Tortoises in the collection of Mr. T. C. Jerdon. The third related to the family *Dermatemydæ*, and embraced the description of a species of this group living in the Society's Gardens. The fourth contained notes on a West African River-Tortoise (*Cyclanosteus senegalensis*), also living in the Society's Gardens. The fifth contained notes on *Bartlettia*, a proposed new genus of freshwater Tortoises, belonging to the family *Peltocephalidæ*, and the sixth notes on the species of *Rhinoclemmys*, in the British Museum. A communication was read from Mr. W. Theobald, containing critical observations on a paper by Dr. J. E. Gray, on the families and genera of Tortoises, which had been recently published in the Society's "Proceedings." Amongst other remarks, Mr. Theobald stated the skull upon which Dr. Gray had established his *Testudo* (*Scapia*) *falconeri*, appeared to have originally formed part of one of the typical specimens of *Testudo phayrei*, in the Indian Museum, Calcutta.—A paper was read by Mr. A. G. Butler, containing a list of Diurnal Lepidoptera, collected by Mr. Spaight in Northern India.—A communication was read from the Rev. O. P. Cambridge, containing descriptions of some new genera and species of *Araneidea*.—A communication was read from Mr. W. Vincent Legge, containing notes on a species of *Prinia* from Ceylon. A communication was read from Surgeon Francis Day, containing a memoir on the Fishes of the Andaman Islands. Mr. Day's list embraced no less than 255 species, chiefly marine, which had been collected during the short space of a three weeks' visit to those Islands.

Linnean Society, Nov. 3.—Mr. G. Bentham, President, in the chair. A paper was read by Dr. Mansel Weale, "On the Fertilisation of certain Orchids and Asclepiads." He described several species of *Habenaria*, some of them new, from South Africa, and explained the process of fecundation, which he believes to be self-fertilisation by the agency of insects. Some of the species, however, fructify comparatively seldom. At night some of the species emit a delicious fragrance, and these are chiefly visited by nocturnal moths. Dr. Weale also contributed a note on a solitary bee from South Africa.

Entomological Society, Nov. 7.—Mr. H. W. Bates, V.P., in the chair.—Mr. T. H. Briggs, of Lincoln's Inn, was elected a member.—Exhibitions of British *Lepidoptera* were made by Mr. Bond, Mr. Howard Vaughan, and Mr. McLachlan; of British *Coleoptera*, by Mr. F. Smith and Mr. Dunning. Mr. Edward Saunders exhibited *Xixuthrus heros*, a gigantic species of *Prionidæ*, from the Feejee Islands. Mr. Albert Müller exhibited galls of *Cynips agama*, and reniform spangles of *Cynips renum*, both on the underside of leaves of the oak.—Communications were read respecting swarms of *Chlorops lineata* which occurred in houses at Cambridge and elsewhere; and respecting the injury done to pear, plum, and cherry trees by the grubs of *Blennocampa Cerasi*.—The following papers were read: "On Butterflies from Basuto-land," by Mr. Roland Trimen; "On *Cerambycidæ* from the Amazons, by Mr. H. W. Bates; "On *Curculionidæ* from Australia," by Mr. F. P. Pascoe; "Notes on the *Eurytominæ*," by Mr. F. Walker.

Anthropological Society, Nov. 1.—Dr. Charnock, V.P., in the chair. Mr. Matthew Heslop, Mr. J. R. Mortimer, Mr. Ankithum Venkata Nursing Row, Mr. James Hope, and Mr. Walter M. Parker, were elected members. Mr. William Storey, M.D., was elected local secretary for Malta; and Mr. Frank Wilson was elected local secretary for St. Paul's de Loanda, W. Africa. A verbal communication was made by Mr. Charlesworth, giving some details of his discovery, and the exhumation, from a Tertiary formation in East Anglia, of a nearly perfect skeleton of one of the gigantic Bovine animals which the Roman legions met with when they first penetrated into the dense forests of Belgium and Gaul, and which are described by Cæsar under the names of *Uri* and *Bisontes*. Dr. R. Charnock, V.P., F.S.A., read a paper on "The People of the Isle of Marken."

Ethnological Society, Nov. 8.—Dr. A. Campbell, Vice-president, in the chair. The following new members were announced:—The Earl of Antrim, Mr. W. Bragge, Mr. H. Rivett Carnac, and Mr. J. E. Lee.—A carved wooden implement found beneath 27 feet of guano in the Island of South Guanape, was exhibited and described by Mr. Josiah Harris. Col. A. Lane Fox exhibited a rudely worked stone implement from Borneo, being the first which has reached this country from that locality.—A note was read from Mr. C. R. Markham relative to the term *Aymara*. He maintained that the people inhabiting the basin of Lake Titicaca were known, at the time of the Spanish conquest, as Collas and not as Aymaras. An elaborate reply to this communication was made by Mr. David Forbes, F.R.S., who showed that the term Colla is merely a geographical expression.—A paper was then read "On the Kimmerian and Atlantean Races," by Mr. Hector McLean. The author described the Atlanteans as a dark race, forming a considerable ingredient in the population of Spain, southern and central France, South Wales, and the south and west of Ireland and Scotland; whilst the Kimmerians were a fair people, often of tall stature, with gaunt features, ruddy complexion, grey eyes, and red or yellow hair. These Kimmerians occupied the British Isles, and mixed with the Atlanteans previously to the arrival of the Scandinavians and Teutons. By means of the names of places, the author traced them in their migrations westwards from their original home between the Don and the Volga. They were known as the Galli or Galatæ, names signifying *white* people. The author concluded that the present population of England is more truly British or Kimmerian than the Welsh, and that our language is not the direct descendant of the language of the Saxon conquerors, but the descendant of both that of the conquerors and a kindred native language. The discussion was sustained by Mr. J. F. Campbell (of Islay), Dr. O'Callaghan, Mr. Hyde Clarke, Mr. Pusey, and Dr. Nicholas.

Chemical Society, Nov. 3.—Prof. Williamson, F.R.S., in the chair. The following gentlemen were elected as fellows:—D. Howard, T. Muter, C. W. Siemens, F.R.S. On opening this first meeting in the new session, the President alluded in a few earnest words to the loss the Society had recently sustained through the death of two of the most distinguished of its members. The following papers were read:—"On the Production of the Sulphates of the Alcohol Radicles from the Nitrites by the action of Sulphurous Acid," by E. T. Chapman. When sulphurous acid gas is passed into nitrite of amyl it is rapidly absorbed. The nitrite changes in colour from yellow to green, from green to blue; it then begins to effervesce, and at the same time becomes hot and boils violently. Nitric oxide is evolved in abundance, and a yellow liquid product remains. This liquid cannot be distilled without decomposition. It contains no nitrogen. When an attempt is made to distil it along with water, the oily liquid found in the distillate consists principally of amylic alcohol. When the liquid is distilled *per se* it blackens, gives off sulphurous acid, and yields a complex distillate which contains, amongst other things, valerianate of amyl. This circumstance stood in the way of any attempt to obtain an insight into the nature of this reaction. Mr. Chapman resolved, therefore to attack the question quantitatively. With this object he determined the nature and amount of the gas evolved by the action of excess of sulphurous acid on a known weight of the nitrite. The result proved that the gas evolved consisted of pure nitric oxide, and that the whole of the nitrogen present in the nitrate escaped in this form. The amount of sulphurous acid necessary to decompose a given quantity of nitrate was also determined by observing the quantity of sulphurous acid which disappeared when an excess of sulphurous acid acted on a known quantity of nitrite. It was then ascertained with sufficient accuracy that one atom of sulphurous acid acted upon two atoms of nitrite of amyl and liberated two atoms of nitric oxide. Lastly, the alteration of weight which nitrite of amyl undergoes by the reaction was determined. The result confirmed the supposition that the reaction consisted in the replacement of two atoms of nitric oxide by one of sulphurous acid.

$$\left.\begin{matrix} C_5H_{11}O.NO \\ C_5H_{11}O.NO \end{matrix}\right\} SO_2 = \left.\begin{matrix} C_5H_{11} \\ C_5H_{11} \end{matrix}\right\} SO_4 + 2\,NO$$

The resulting liquid compound had therefore the composition of neutral sulphate of amyl. It readily breaks up into amylic alcohol and sulphuric acid by boiling with water and by long standing even with cold water; treated with strong hydriodic acid it yields sulphuretted hydrogen, water, iodine, and amylic iodide; potassic bichromate and sulphuric acid cause it to yield valerianic acid. It is to be observed that it is necessary gently to warm the retort in which the nitrite is exposed to the action of a stream of dry sulphurous acid; if this is not done, the SO_2 is absorbed for some time without any reaction occurring, but when the reaction does start it is with almost explosive violence; whereas, if gentle heating has been applied from the beginning, the reaction starts at once and goes on regularly. It is also desirable to pass through the apparatus carbonic acid or hydrogen before the SO_2 has been passed into the nitrite, and to do this also afterwards, for the purpose of excluding air, the oxygen of which would unite with the NO, and the SO_2 would then be expelled. Sulphurous acid and butylic nitrite react upon one another in a manner analogous to that of SO_2 or amylic nitrite, but the resulting product is even more unstable. Sulphurous acid and nitrite of ethyl do not readily act upon each other, at least not at the common temperature. Mr. Chapman then proceeded to the theoretical considerations which are suggested by the above facts. Are these compounds, properly speaking, sulphates of alcohol radicles, or only bodies isomeric with them? The reaction of the amyl compound with water is very different from that of sulphate of ethyl under similar circumstances; it does not, when boiled with water, form an acid analogous to isethionic acid, but splits up into sulphuric acid and amylic alcohol. This would suggest a different linking of the molecules; most probably in the common amylic sulphate the two organic radicles are linked to oxygen directly, and by oxygen to sulphur; in the amyl compound obtained from the nitrite, one of the radicles is attached directly to sulphur and the other indirectly through the oxygen. Mr. Chapman then described the apparatus by which the nature of the reaction of sulphurous acid on amylic nitrite has been determined. The evolved nitric oxide was transformed into nitric acid, and this treated with barytic carbonate. In the discussion following this paper, Dr. Debus and Mr. Harcourt expressed their apprehension that along with the barytic nitrate also some barytic nitrite may have formed. Mr. Chapman replied that he had taken great care to ensure the complete transformation into nitric acid; that to this end he had passed great quantities of oxygen into the collecting cylinder, let the mixture stand for twenty-four hours over the water in the cylinder, and lastly applied gentle heat to it. As for the possibility of the water acting as a base and reducing the formed nitrous acid, there was the counteracting presence of SO_2, which had passed unabsorbed through the amylic nitrite into the collecting cylinder, and part of which must have been oxydised to sulphuric acid. Regarding Mr. Chapman's theoretical views of the union of SO_3 and $\left.\begin{matrix} C_2H_5 \\ C_2H_5 \end{matrix}\right\} O$, the President thought that it is the same as that of SO_3 with H_2O, that the two C_2H_5 are linked to SO_3 by the oxygen, just like the two H are in hydric sulphate.—Mr. Vacher read a paper by Mr. Elliott "On the determination of Sulphur in cast-iron." This determination consists in the liberation of the sulphur in the form of sulphuretted hydrogen, absorption of the latter by solution of soda and estimation of the H_2S in the acidified soda solution by means of a standard solution of iodine. In the course of his experiments, Mr. Elliott noticed that a portion of the iron was not attacked by HCl, and that this insoluble residue yielded on fusing with pure caustic soda (prepared from sodium) sodic sulphate. From this Mr. Elliott draws the conclusion that cast-iron contains sulphuric acid as well as sulphur. In somewhat similar manner the presence of phosphoric acid in cast-iron was ascertained. Dr. Debus doubted the probability of the occurrence of sulphuric acid in iron which had once been in a molten state. Mr. Church remarked that he had noticed in dissolving natural pyrites in HCl, that very often an insoluble sulphide and phosphide remained. At the same time, he considered the fusion of those residues with caustic alkalis as a sure means of converting the sulphur and the phosphorus into the respective acids, the alkalis being under such circumstances very powerful oxydising agents. Mr. Harcourt expressed his concurrence with Mr. Church's remarks about the oxydising action in this case of caustic soda. Mr. Vacher did not wish to support Mr. Elliott's view about the presence of sulphuric acid in cast-iron, but there was the fact of one portion of the sulphur not being liberated by HCl, and this forces to the conclusion that cast-iron contains sulphur in another form than in that of the ordinary sulphide.—E. A. Letts, "On the Composition of Hyposulphites." Though the salts of the hyposulphurous acid have been comparatively well studied, much difference exists as to their chemical constitution. Rose states that an atom of water is retained by all the hyposulphites, and is essential to their composition. On the other hand, Pope and other chemists maintain that most, if not all the hyposulphites, can be obtained in the anhydrous condition. Mr. Letts undertook some experiments to ascertain whether hydrogen was to be regarded as an essential constituent of the hyposulphites. The salts submitted to investigation were those of sodium, barium, lead, strontium, magnesium, nickel, and cobalt. The sodium salt lost all its water by drying *in vacuo* over sulphuric acid. The barium salt gives off its water by drying at 100° C. The plumbic hyposulphite, prepared by adding a solution of lead acetate to one of sodic hyposulphite, crystallises out from the liquid without any water at all. This, then, is a case demonstrating without doubt that hydrogen is *not* needed to complete the chemical constitution of a hyposulphite. The strontium salt retained, even after drying at 200° C., half a molecule of water. The magnesium salt crystallising with six atoms of water, loses three of them at 100° C.; but an attempt to expel more water causes the decomposition of this salt. The nickel hyposulphite, the crystals of which have also six H_2O, do not part with any of it without undergoing decomposition. The cobaltic hyposulphite is even more unstable than the former salt. The President observed that the contents of the last paper set at rest the doubts which hitherto existed as to the constitution of the hyposulphites, and showed that the water which they ordinarily contain is not essential to their chemical existence.

BERLIN

German Chemical Society, October 10.—President, Prof. Rammelsberg. The President reported on the means employed by the society to promote disinfection of the battle-fields and hospitals. A great number of German and foreign chemical manufacturers had kindly responded to a circular requesting gifts of chemical disinfectants. From England, Messrs. Berger, Spence, & Co., Ballman and Condy, F. C. Calvert & Co, Crowther and Graeson, L. Demuth & Co., C. Kurtz and Sons, C. Lowe and Co., G. Lunge, George Miller and Co., T. Storey and Co., had sent various disinfecting agents. A table detailing the right use of disinfectants had been published and sent to the proper medical authorities and members of the society who have undertaken the superintendence of disinfection in various towns. The seat of war has been visited for the same purpose by six members of the society. The following papers were then read:—A. W. Hofmann: "The history of Nitriles," a reply to M. Mendelejeff, who had published certain views, not knowing the same to have been promulgated before by the author.—T. Thomson: "On the double chloride of Beryllium and Platinum." This salt is isomorphous with the corresponding calcium salt, and not with the magnesium salts, as had been supposed. The same author on "The supposed Connection of the law of Avogadro with the Mechanical Theory of Heat." A mathematical deduction lately published by Naumann, contains, according to Thomson, an error invalidating its argument.—C. Rammelsberg, in a lecture on the relation of mineralogy and chemistry, urges upon mineralogists to apply the modern formulæ.—A. Bauer described an alloy of lead and platinum of the formula Pt Pb.

October 24.—H. Wichelhaus described β Nitronaphtol. This compound, which cannot be produced in the ordinary way, may be obtained by treating alcoholic solution of β naphthol with nitric acid, as was lately recommended by Bolley. The same chemist has obtained Triacetamide by applying a similar method to that employed by Kekulé in the preparation of diacetamide. The latter is obtained by acting on acetonitrile with acetic acid; the former by replacing the acid by acetic anhydride: $CH_3 CN + (C_2 H_3 O)_2 O = (C H_3 C O)_3 N$. The three amides have nearly the same physical properties. The diamide, according to Kekulé, forms salts. The triamide is an anhydride converted by $P_2 O_5$ into acetonitrile and acetic anhydride.—Petersen on Nitrochlorophenoles. By continuing the researches of Baer-Predari, the author has produced five of the six possible isomeric bodies of the above constitution.—C. Rammelsberg, on Yttrocerite, determines the formula of the mineral Ce F_2, 2Y F_2, 9 Ca F_2, 3 aq. Berzelius had found 1 Y 2 Ce. Both Y and Ce represent rather groups of metals than well-defined single elements. In a discussion following this communication, G. Rose called attention to the isomorphism of yttrocerite and fluorspar, thinking that most likely the water found in the former ($2\frac{1}{2}$ per cent.) does not form a constituent part of the mineral.

THE CLAIMS OF SCIENCE

THE Statistical Society, which held its first meeting for the session 1870-71 on Tuesday, the 15th inst., had the claims of Science brought before it in a paper read to it by Dr. Guy, one of its vice-presidents. The paper was written with the practical aim of commending and furthering a scheme which the Statistical Society has set on foot, and in which it has invited the Institute of Actuaries, the Social Science Association, and several other scientific bodies, to participate. The object these societies have in view is to provide a common home in which they shall enjoy the advantage of fixity of tenure and the sense of permanence, with suitable and economical arrangements for carrying on their scientific work. They wish to provide for themselves a common theatre, convenient offices, spacious libraries, and—in the case of societies requiring moderate museum accommodation—museums. All this the societies aim at accomplishing within moderate limits and at a reasonable cost; for they feel very naturally that when the Government has made provision at Burlington House for six leading societies, and other institutions have provided their own isolated accommodation, there no longer remains any place or pretence for a large and comprehensive scientific centre. The building contemplated by the associated societies would have all the unity of character now practicable, if its principal tenants were to consist of societies having a common aim. Such an aim is to be found in the culture of the sciences now known as "social," or societies which make man himself, as the unit of society, the object of their study.

If we define Science as "knowledge in its most definite, condensed, and exquisite form, dealing with worthy objects, and applied to worthy uses," it may be stated, as a truth worthy of general acceptance, that every branch of knowledge that is, by common consent, stamped with the word *science*, aims at some useful and worthy object, studies a certain defined order of things, which it identifies by accurate descriptions and exact definitions, by expressive words and phrases; which it arranges in lucid order, under classes and sub-classes; on which it brings to bear the most delicate instruments and most refined methods of analysis; to which it applies, as far as practicable, the rules of logic and the figures of arithmetic; crowning the entire edifice, if it proves equal to the burthen, with some comprehensive numerical theory.

Passing from this general view of science, and coming to that branch of it now known as *social*, we may trace the seeds of it back to the parish registers of 1538 and the enactment of Henry VIII., respecting leases for three lives, or twenty-one years, through the London Bills of Mortality and the commentaries of Grount and Petty, through the early attempts of Halley to construct a table of mortality from the death registers of Breslau, through the prison inspections of John Howard, up to the establishment of the Statistical Society in 1834, and the foundation of the Social Science Association in 1857; the Statistical Society having, as is well known, been set on foot with the object of collecting "facts calculated to illustrate the condition and prospects of society," which was what Gottfried Ochenwall, of Göttingen, who coined the word *Statistik*, really meant by that word. The Social Science Association, therefore, was a second development and a modified culture of that branch or division of human knowledge—that science of States—to which had been previously given the name of Statistics. The two societies have a common aim—the improvement of man's condition physical, intellectual, and moral, through the patient heaping up, intelligent sorting, and critical examination of the elements of a knowledge which, properly applied, is power indeed.

This social science, of which the *Institute of Actuaries* cultivates a very important section, differs from most other sciences chiefly in this, that its units are of variable magnitude, and that its truths and principles, gathered from large assemblages of such units, admit of application only to like collections of facts, not to the individual units themselves. The actuary has the function of first establishing truths of this order, and then applying them; the statist must look to the statesman to carry into effect the practical works of justice and benevolence. The association of the Statistical Society and Institute of Actuaries with the Social Science Association and Law Amendment Society is, therefore, one pointed out by the nature of things; and we may hope to see them some day working side by side under one roof with one common aim—"*the improvement of man's estate.*" But this principle of association admits of being carried much farther, so as at length to embrace in one group, under one roof, all the societies or associations that make man himself, as a physical and moral unit, the object of their study.

The section of Dr. Guy's paper that treated of *scientific societies and associations*, consisted of an historical retrospect of the rise and origin of most of the societies now existing, finishing with some details of the number and composition of the Statistical Society's members, and of the number of members of the allied societies. Into these details we shall not enter, but we shall restrict ourselves, in what we have yet to say, to the views expressed by Dr. Guy on the subject of the claims of science to public recognition and support. After pointing out that science has found favour, encouragement, and support under every form of Government, that kings have acknowledged that it adds lustre even to thrones, and republics have deemed it quite consistent with their sterner virtue to hold out to it the hand of fellowship—a recent notable example of which has been afforded in the pecuniary assistance and means of transport afforded by the United States to two parties of its citizens bent upon voyages to Spain and Sicily to view the total eclipse on the 22nd of December, an example which our Government has at last, however, willingly consented to follow,—the paper proceeded to do justice to our own Government. The refusal, followed by a slow repentance, was quite an exception to the rule in England. It could only have occurred during one of those cold fits of economy to which the nation is subject at the close of some feverish paroxysm of prodigal expenditure; or it may have been an outbreak of the hypochondriac fancy that they are on the brink of ruin, which is apt to seize the richest nations no less than the wealthiest individuals. It is not difficult to show that Science, in the sense of knowledge of the more precise, exact, and exquisite order, has claims to public recognition and support on the ground of benefits conferred on the nation in the shape both of honour and profit; that it shares with righteousness the prerogative of exalting a nation (for the love of truth, which causes men to seek after knowledge and the patient industry and self-denial which are the first conditions of the search, are among the manly virtues that give strength and solidity to a people); that it must be preferred before learning, as being more practical, and coming into more direct contact with the realities of life; before art, as less apt to be turned to unworthy uses, more sure not to become an agent of effeminacy and luxury.

Of the good gifts which Science showers upon mankind, we may find grand and convincing examples in the works of the hygienic heroes of the last century—Sir George Baker and his masterly demonstration of the cause of the Devonshire colic, Captain Cook and his successful prevention of scurvy, John Howard and his prison work, ending in the destruction of the Jail Fever, and Jenner, with his discovery of vaccination. We fully sympathise with the concluding words of this part of our author's paper:—"By what figures of arithmetic shall I attempt to measure the greatness of these four gifts of science, freely bestowed upon us, and upon all men everywhere, in the short space of a single generation? I believe it to be no exaggeration to affirm that the great war of the French Revolution was brought to a successful issue as much through the lives thus saved as by the valour of our soldiers and sailors. Such have been the triumphs, such the precious gifts, of this one science of hygiène." Other illustrations of the same class, that is to say, showing direct profit to the nation, may be drawn from the Science of Chemistry, of which the whole history, from first to last, is one unbroken series of purely scientific discoveries made for love of truth, without thought or hope of reward, but, sooner or later, turning to profit in the hands of our manufacturers.

We might cite examples from the discoveries of Davy and Daniell, and the arts of electrotyping and photography, discoveries appealing to universal experience of the manifold obligations under which science and scientific men have laid mankind for all the arts which make our civilised existence to differ from the rude life of the savage. The Penny Post, with its world-wide benefits, is the result of a scientific demonstration belonging to the methods and domain of Social Science.

We conclude with the following statement of the special claims of the Statistical Society and its associates in the culture of Social Science:—"The scientific labours of our members, inspired by a mere love of truth, looking to no pecuniary reward, and bearing directly on the very questions which come under discussion in the Legislature, are in many cases a direct saving of expense to the nation. An important (perhaps a very costly) return is made to Parliament. It abounds in tables and columns of figures. The work of analysis, which must be undertaken if the return is not to become so much waste paper, if Parliament and the public are to profit by the expense incurred—this work of analysis is done by some member of the society seized with a wholesome curiosity to know the truth. He bestows upon it time, and thought, and the skill acquired by practice; he submits his work to the criticism of the Society, his paper is published in its *Journal*, at its proper cost; and thus the public and the Government save money and become possessed of wholesome and fruitful truths." These are claims which, we think, the Government will feel bound to recognise, and we wish the cultivators of the Social Societies every success when they come to represent them in the proper quarter.

THE SOURCES OF PHOSPHATIC MANURES

"PRACTICE with Science" is the title of a volume of essays (the second of a series), issuing from the Royal Agricultural College, Cirencester, and containing contributions from the members of the staff of that institution. Amongst other papers is an interesting account by Prof. Thiselton Dyer of the geological distribution of Tricalcic Phosphate; that is to say, a sketch of the chief sources of mineral phosphate of lime, whether as apatite, osteolite, phosphatite, coprolite, or guano. Mr. Dyer points out the abundance of phosphate of lime in igneous rocks, but hesitates about tracing its origin in such beds either to direct chemical combination, or to the inclusion of organically-formed phosphate in the rocks in question. He does not, in short, discuss the possibility of the combination of phosphoric acid and lime in the primæval state of the globe without the intervention of life, which one distinguished geologist at least denies. Mr. Dyer traces the occurrence of tricalcic phosphate in the various sedimentary deposits with great care, having obviously taken much trouble to render his statement an exhaustive one. He considers the many structureless masses of phosphatic deposits which occur "as residuary evidence of formerly existing life, of which they are to some extent the measure," as graphite is in other cases. A greater influence in the production of these masses is attributed to animal than to vegetal life, though marine plants are stated to be especially rich in phosphate of lime, and have undoubtedly played their part in its introduction into sedimentary strata. Mr. Dyer mentions that the recent Brachiopod Lingula has 86 per cent. of phosphate of lime in the mineral ingredients of its shell; and the occurrence of large quantities of phosphate of lime in the great Laurentian and Silurian formations is noticed by him in detail, as well as its occurrence in Devonian and Carboniferous limestones. In emerging to the group of mesozoic strata, we leave behind almost entirely those veins and beds of "phosphate" which occur in the older and more changed rocks, where the segregation of the phosphate of lime has been more completely effected, owing to the greater age of the beds. In mesozoic and tertiary strata we find those nodules which have so erroneously been confused with "coprolites"—the droppings of fish, which are not unfrequently preserved in the fine sediment of the Liassic and the Rhætic beds of the chalk—though beds of flaggy phosphate also occur in some deposits of this age.

Mr. Dyer accepts the history of the origin of these nodules which I have advocated (Geol. Magazine, vol. v.), in describing those which occur below the Suffolk Crags. Clay has a remarkable power of detaching phosphate of lime from its solution in carbonated water; and the phosphatic nodules are bits of clay which have become imbedded with great quantities of bones, and in some cases, very probably—as suggested by Mr. Seeley, of Cambridge, with regard to the Cambridge nodules—with sea-weed too; whence, by the intervention of gas-charged water, they have extracted the phosphate: hence all beds of phosphatic nodules occur near to argillaceous strata of special character. Much of this process, no doubt, went on whilst the bones and clay-lumps lay on the ancient shores, and were daily washed and infiltrated by the sea-water, or lay entirely submerged in masses: but Mr. Dyer thinks that the process of transference would continue after the beds had been left high and dry, and may be now going on; though I think it is clear that the phosphate of lime in the nodules came from bones which have been destroyed and lost in the process, having been very different in mineral condition to the fragments which now remain amongst the nodules of these valuable "bone-beds." Mr. Dyer notices Rhætic, Jurassic, Cretaceous, and Tertiary accumulations of phosphatic nodules. There is one which has not been hitherto recorded, and which is not alluded to in this paper, but is interesting, and in a well-known locality; it occurs in the Wealden series, near Brook, in the Isle of Wight, and is in parts five or six feet thick. The nodules are light-coloured, and aggregated into masses so as to form a solid bed, and not a pebbly conglomerate, as is usual.

The distribution and origin of Guano is briefly given. True guano is simply the dung of sea-fowl, and can only accumulate in rainless districts. Guano rock is the result of the action of water on this matter and subjacent calcareous coral rocks; the celebrated Sombrerite is of this nature. It is very possible that much of the palæozoic phosphatic rock may have been produced in this way, in those beds, at any rate, which we may believe to have been formed subsequently to the evolution of terrestrial vertebrate forms of life.

The other essays in this volume treat of more strictly agricultural subjects, and are accordingly of more limited interest. E. RAY LANKESTER

SCIENTIFIC YEAR BOOKS

The Year-Book of Facts in Science and Art. By John Timbs. Pp. 288. (London: Lockwood and Co., 1870.)

Annual of Scientific Discovery, or Year-Book of Facts in Science and Art for 1870. Edited by John Trowbridge, aided by Samuel Kneeland, M.D., and W. R. Nichols. Pp. xxii. and 354. (Boston: Gould and Lincoln; London: Trübner and Co., 1870.)

L'Année Scientifique et Industrielle. Par Louis Figuier. Quatorzième Année (1869), pp. 606. (Paris: Hachette; London: Williams and Norgate, 1870.)

Causeries Scientifiques. Neuvième Année (1869). Par Henri de Parville. Pp. 363. (Paris: Rothschild; London: Williams and Norgate, 1870.)

Annuaire Scientifique. Par P. P. Dehérain. Neuvième Année (1869), pp. 387. (Paris: Masson; London: Williams and Norgate, 1870.)

Jahrbuch der Erfindungen. Herausgegeben von H. Hirzel, und H. Greschel. Fünfter Jahrgang, pp. 416. Leipzig: Quant; London: Williams and Norgate, 1869.)

GROUPING these volumes according to the languages in which they are written, we may dismiss the first two with a very few remarks. Mr. Timbs literally gives his readers nothing whatever but a collection of cuttings from the most miscellaneous sources, including the *Pall Mall Gazette, Times, Spectator, Illustrated News, Liverpool Albion,* &c.; while Mr. Trowbridge and his coadjutors (who have a respectable scientific status) present us with a much more perfect, although still an incomplete, picture of the leading discoveries of the year. The introductory notes by the Editor constitute the most valuable portion of the American book, which treats of the progress of science, under the respective heads of (1) Mechanics and Useful Arts, occupying 135 pages; (2) Natural Philosophy, to which 64 pages are devoted; (3) Chemistry, (4) Geology, (5) Biology, (6) Astronomy and Meteorology, and (7) Geography and Antiquities. This volume, like that of Mr. Timbs, exhibits a too free use of the scissors, but the extracts are almost invariably taken from periodicals of good scientific repute.

If our readers require any specific evidence of the English editor's unfitness for his office, we would refer them to the article headed "Singular Plant," in p. 200 of the "Year-Book of Facts." It is obvious from the most cursory perusal of the history of this "singular plant," that it is merely a fine specimen of coral, and the absurdity of the story was exposed in a number of the *Gardener's Chronicle* subsequent to that in which it originally appeared. The correction was, however, overlooked by the learned editor.

The French Year-Books differ materially from one another in their modes of arrangement. In this respect we prefer that of M. Figuier to the others. It includes a large number of subjects arranged in the following order:—Astronomy, Mechanics, Physics, Meteorology, Chemistry, Civil Engineering, Voyages and Travels, Natural History, Public Health, Physiology and Medicine, Agriculture, and the Industrial Arts.

The science-gossips of M. de Parville are a collection of papers such as a physicist might contribute to a popular journal. The matter in this volume is more digested, and is in a far less crude and fragmentary state than in the other books we have noticed, and the individual facts are dovetailed together so as to make the style agreeable and the reading continuous. It includes in its range—Astronomy, Physics, Mechanics, Chemistry, Physiology and Medicine, Natural History, Engineering, and unplaceable topics.

In some respects M. Dehérain's volume is the best of the three. Although less comprehensive in its scope than that of M. Figuier, or even than that of De Parville, it is more perfect so far as it goes. It is divided into two parts, treating respectively of the pure and of the applied sciences. Under the pure sciences he places Astronomy, Physics, Chemistry, Meteorology, Botany, Physiology, and Anthropology; while the applied sciences include Civil Engineering, Applied Chemistry, Medicine, and *Exploitation des Animaux,* for which we have no exact English equivalent. It is, we think, doubtful whether this sub-division of the sciences will bear criticism, but it is needless at present to discuss that subject. Instead of flying from flower to flower like the busy bee of our early days, M. Dehérain confines himself to one or two of the most important subjects in each department, and these he treats with far more fulness than the preceding writers. For example, under Chemistry we have an article on Explosive Compounds, containing a review of the works of Nobel, Abel, Berthelot, and Saint-Claire Deville, by the editor; and another, by M. Laudrin, on the Influence of Pressure on Chemical Phenomena, being a review of the works of MM. Berthelot and Cailletet; and these, with a biographical sketch of Professor Graham, complete the section on this science. Similarly, the only information that he gives us on Botany is included in an article by M. Vignes on the Geographical Distribution of Vegetable Species, based on the works of Sir Dalton Hooker (*sic*), and an article by himself on the Maturation of the Cereals.

Amongst the subjects most fully considered by MM. Figuier and De Parville are the Suez Canal; the cause of the explosion in the Place de Sorbonne, and the recent history of picrates and other explosive compounds; the discussion regarding the modification of the metre; the Newton-Pascal forgeries; chloral and its action; and the deleterious effects of absinthe. The question whether Coralline (one of the coal-tar colours) is or is not deleterious as a dye is fully discussed in the volumes of MM. Figuier and Dehérain.

Although it is less extensive in its range of subjects, we are inclined to prefer Hirzel and Gretschel's "Year-book of Inventions" to any of the preceding volumes. The departments of science which it includes are Astronomy, Physics and Meteorology, Mechanics and Mechanical Technology, and Chemistry and Chemical Technology. With the view of briefly explaining the arrangement adopted by the editors, we may state that under "Physics and Meteorology" are included molecular physics, acoustics, optics, the theory of heat, and electricity and magnetism. Under the heading "Mechanics and Mechanical Technology," only five subjects are considered, but they are all treated in considerable detail. They are—dynanometers, mechanism applied to locomotion (including the mountain railway system of Marsh and Fell, the road engines of Larmanjat and Thompson, velocipedes, and Kettendampff-schifffahrt or chain-steam-navigation), sewing and knitting machines, to which more than thirty pages are devoted, and new pumps constructed on various principles. This work is executed in a higher scientific spirit than any of the preceding volumes, excepting, perhaps, that of M. Dehérain.

It would carry us far beyond the proposed bounds of the present article if we were to notice, however briefly, the various German Year-Books that are devoted to special subjects, and some of which—as for example the great Year-Book of Chemistry founded by Liebig and Kopp—are complete histories of the science of which they treat. There are, however, two French Year-Books of this class, of comparatively small size, that are deserving of notice, and which we can strongly recommend to the notice of our readers, namely, M. Micé's "Rapport sur le Progrès de la Chimie Organique," of which only one volume has yet appeared, and M. Vivien de St. Martin's "L'Année Geographique," of which the eighth volume, for 1869, is now lying before us. Both of these works are models of what such volumes ought to be, and show an immense amount of labour on the part of their respective editors. We should be very glad to see something like "L'Année Geographique" attempted in this country, where we have no summary of the annual progress of geographical progress, excepting the necessarily imperfect summary contained in the anniversary address delivered by the President of the Geographical Society. G. E. D.

OUR BOOK SHELF

An Elementary Course of Botany; Structural, Physiological, and Systematical. By Prof. Arthur Henfrey. Illustrated by upwards of 500 Woodcuts. Second Edition, revised, and in part re-written, by Maxwell T. Masters, M.D. (Van Voorst: 1870.)

We heartily welcome a new edition of this standard work, brought fairly down to the present state of knowledge by one of our most active and conscientious botanists. We have not yet had time to collate the present edition with the original. Cutting the pages (what an unnecessary nuisance this is in lesson-books!), no criticism worth noting occurs to us, unless it be by way of protest against the double index—one of plant-names, the other general and glossarial. This is certainly worse than letting the book into the market uncut! Had the work been new and original, other comments would not have been wanting; as it stands, we can only congratulate the editor on the very satisfactory way in which he has accomplished his work. By the way, with regard to starch, about which Prof. Henfrey was rather strong, we can imagine the sort of haze a student who had been grinding from this edition (pp. 495-496) would manifest in his paper, were he asked to state something of the origin of that substance. Not that there is any inaccuracy in the book, but rather because possession of a greater amount of preliminary knowledge than it is reasonable to look for seems to be taken for granted. Some hint might have been given as to the head-quarters of Aleurone. Lastly, we should have preferred seeing *Amphisarca*, *Tryma*, *Diplotegia*, and their kin quietly dropped out of the edition. We doubt if there be a professor of botany in the island worth his salt who could define them. D. O.

Sketches of Creation. A Popular View of some of the Grand Conclusions of the Sciences in reference to the History of Matter and of Life. By Alexander Winchell, LL.D. (London: S. Low, Son, and Marston, 1870.)

The main portion of this volume is occupied by a sketch of the geological history of the earth; and had Prof. Winchell confined himself within strictly scientific limits, the book would have been one in every respect commendable. The titles of some of the chapters are sensational and repellent, *e.g.* "The Ordeal by Fire," "The Solar System in a Blaze," "Onward through the Ages;" and we could have wished that the author had kept aloof from speculations which are, to say the least, not profitable to the class to whom the book is addressed—on the former gaseous condition of the world and the solar system; and on the possible evolution of an animal superior to man. These parts being eliminated, the book may be safely relied on as the work of a practical geologist, who has a thorough acquaintance with his subject; and being laudably free from the excessive use of technical terms, occupies a place not precisely filled by any English treatise. The illustrations are numerous, and very various in quality. The drawing of Fingal's Cave at Staffa is a grotesque caricature; with others we are familiar in well nigh every geological handbook; especially interesting to English readers are those illustrative of the gigantic scale of geological action in the United States, as the Pictured Rocks of Lake Superior, and the Mauvaises Terres of Dacotah. Two chapters "On the Vitality of buried Vegetable Germs," and "On Prairies and their treelessness," have special reference to Prof. Winchell's well-known theory that the present vegetation of the prairies of America is lineally descended from that of the preglacial epoch, the seeds having retained their vitality in the ground during the whole of the intermediate time. We cannot admit that the instances quoted by the author of vegetable tissue retaining its *structure* during an enormous lapse of time, when not exposed to the oxidising influence of the air, have any bearing on the question whether germs can retain their *vitality* for the same lengthened periods; as he himself says, the proof of the theory ought to rest on direct evidence: "It must be confessed that the crucial observation has yet to be made; if vegetable germs exist in the drift, they can be discovered beforehand. I am not aware that any thorough search has ever been made for them."

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

The Difficulties of Natural Selection

MR. Wallace's "Reply" has disappointed me. From his unrivalled knowledge of the forms of animal life in those countries where nature is the most luxuriant, and from the extraordinary interest with which he invests every subject that he handles, I had expected from him something more conclusive than that he should charge his opponent with errors which he has not committed, and should reply to his arguments by a simple begging of the question.

The first "important error" with which Mr. Wallace charges me is, that "I lead my readers to understand that there is only one completely mimicking species of *Leptalis.*" Where I have done so, I am unable to discover. I have, it is true, adduced one particular and striking instance as a sample of the rest, but distinctly say that "in a comparatively small area, several distinct instances of such perfect mimicry occur;" and point out how strongly, in my view, this tells against the theory of Natural Selection. In the next paragraph, "three great oversights" are alleged. Firstly, "that each *Leptalis* produces not one only, but perhaps twenty or fifty offspring." Mr. Wallace can hardly have supposed that I imagined each butterfly laid only a single egg, like the rok. The argument, however, is unaffected. In a species the numbers of which do not materially vary from year to year, it is obvious that, whatever the number of eggs laid, only one offspring from each individual, or rather two from each pair, survive to the period at which they themselves produce offspring. The "second oversight" is "that the right variation has, *by the hypothesis*, a greater chance of surviving than the rest; and the third, that at each succeeding generation the influence of heredity becomes more and more powerful." By what hypothesis? The hypothesis that these small variations in the right direction are useful to the individual—the very hypothesis against which I am contending as unproved; as neat a case of *petitio principii* as one often meets with. My "errors" in fact, amount to a non-admission of my opponent's premisses, who then naïvely adds, "with these three modifications the weight of the argument is entirely destroyed!" Of course it is. The "new factor of which I take no account" in the next paragraph, is again entirely dependent on the admission of the natural selectionist premisses.

With regard to the distinction between man and other animals, I much regret if I have unwittingly misrepresented Mr. Wallace's view; but if I have done so, I think it is owing to that view not having yet been clearly pronounced. Mr. Wallace distinctly states his opinion that "a superior intelligence has guided the development of man in a definite direction." ("Contributions," p. 359.) I have Mr. Wallace's own authority for saying that M. Claparède has misinterpreted him in referring this superior intelligence to a "Force supérieure," a direct action of the Creator; what alternative is there left but to suppose that it was man's own intelligence that he had in view? Whenever Mr. Wallace more clearly enunciates this portion of his theory, I think there will be no difficulty in showing that the same principle, whatever it may be, is operative in the lower creation as well as in man.

Having disposed, as I think, of Mr. Wallace's chief points of reply, I may be permitted to point out one or two errors into which he has himself, it seems to me, fallen. The changes of mimicry are, he says, "wholly superficial, and are almost entirely confined to colour." I was certainly surprised to read this, recollecting so many instances to the contrary, not only among tropical insects, but in the close approximation in form of some of our own Diptera to certain genera of Hymenoptera; and recollecting also the numerous illustrations of protective form and habit which Mr. Wallace himself gives, not only describing them but having also drawn them with such exquisite fidelity. (See "Malayan Archipelago.") In the *Kallima paralekta* of Sumatra, for instance, he says, "we thus have size, colour, form, markings, and habits, all *combining together* to produce a disguise which may be said to be absolutely perfect." ("Contributions," p. 61). Another sentence I had to read three or four times before I could believe that Mr. Wallace had penned it. In objecting to my parallelism between the development of protective resemblance and of instinct, he says, "in birds mimicry is very rare, only two or three cases being known." I do not know whether Mr. Wallace draws any subtle distinction between "mimicry" and "protective resemblance;" but if so, he should have noticed that it is the latter which I speak of as "being strongly developed in birds." I had, on reading the above sentence, to turn again to my "Contributions," to see whether I was correct in my impression that we find there the statement that "in the desert the upper plumage of *every bird* without exception is of one uniform isabelline or sand colour;" that "the ptarmigan is a fine example of protective colouring" ("Contributions," pp. 50, 51), and that two whole chapters are devoted to the wonderful protective instinct of birds in the matter of their nests.

On one point raised in my paper I am disposed somewhat to modify my views, and I do so with the greatest pleasure, in my objection, namely, to the title of Mr. Darwin's great work. Taking the origin of *species* as distinct from the origin of mere *varieties*, there is undoubtedly a sense, as Mr. Wallace points out, in which natural selection may be considered a prime factor. The law of variation is a centrifugal, the law of natural selection a centripetal force; the one acting by itself would produce a wild chaos, the other a barren uniformity: equilibrium can only be the result of their joint co-operation.

Whatever may be my "inability to grasp the theory," I hope I have shown that I have not fallen into the errors with which Mr. Wallace charges me. All the main points of the argument seem to me to be left untouched by him. He has brought forward no evidence that extremely small variations do afford any immunity from the attacks of enemies. He gives no explanation of the tendency of the *Leptalis* referred to by Mr. Bates "to produce *naturally* varieties of a nature to resemble *Ithomiæ*." He does not attempt to account for the parallelism of the development of protective resemblance and of instinct in the animal world. He fails to explain the nature of the intelligence which was operative in the creation of man, and which is a principle unknown in the rest of the organic world. Students of Nature who have spent their lives in their own country must always yield in point of experience to those who have had the advantage of comparing the faunæ and floræ of other climates, and can only arrive at their conclusions from the facts brought to their notice by travellers; these, I think, I have not misrepresented. Appeal to authority, as authority, is always to be deprecated in Science. I may, however, perhaps be permitted to strengthen my position by a quotation from a work, which I had not read at the time of writing my paper, by one who will be acknowledged to have some knowledge of the ways of Nature (Huxley's Lay Sermons, p. 323):—"After much consideration, and with assuredly no bias against Mr. Darwin's views, it is our clear conviction that, as the evidence stands, it is not absolutely proven that a group of animals, having all the characters exhibited by a species in Nature, has ever been originated by selection, whether artificial or natural."

ALFRED W. BENNETT

Westminster Hospital, Nov. 19

P.S.—Since writing the above, Mr. Jenner Weir has kindly called my attention to two papers read by him before the Entomological Society, "On the Relation between the Colour and the Edibility of Lepidoptera and their Larvæ." In one of these I find the following remarkable statement:—"Insectivorous birds, as a general rule, refuse to eat hairy larvæ, spinous larvæ, and all those whose colours are very gay, and which rarely, or only accidentally conceal themselves. On the other hand, they eat with great relish all smooth-skinned larvæ of a green or dull brown colour, which are nearly always nocturnal in their habits *or mimic the colour or appearance of the plant they frequent.*" Here at least it would seem as if *imperfect* mimicry was anything but beneficial to the individual; how can the principle of natural selection account for its propagation in these instances?

THE soul of many an anti-Darwinian will have been cheered by Mr. A. W. Bennett's paper on "The Theory of Natural Selection from a Mathematical Point of View." It is, in fact, a very admirable piece of special pleading, based on a skilful assumption of premisses which, to a careless or biassed observer, might seem indisputable.

The tendency to variation is spoken of as something very mysterious, of which no adequate account has ever yet been given. Yet the very simple explanation is no bad one, that where two parents are concerned in the production of any offspring, the product in part resembling each of the producers must of necessity also in part differ from each of them. Between the parents themselves, Mr. Herbert Spencer has shown that differences of age and external circumstances would ensure the requisite want of resemblance in the absence of any other cause.

"The rigid test of mathematical calculation" is then applied to the case of mimetic butterflies, with the view of showing that they could not have been produced simply according to the laws of variation, inheritance, and natural selection. In the application of this rigid test the very first step is a perfectly gratuitous assumption, "that it would require, at the very lowest calculation, 1,000 steps to enable the normal *Leptalis* to pass on its protective form." Who is to prove that fifty differences would be insufficient? An interval of a thousand years might be granted for establishing each one of these variations. Suppose even 50,000, instead of only 50 steps to be necessary, it is another gratuitous assumption that "the smallest change in the direction of the *Ithomia*, which we can conceive in any hypothesis to be beneficial to the *Leptalis*, is at the very lowest one-fiftieth of the change required to produce perfect resemblance." How small a difference must decide the choice made by a donkey placed equidistant between two bundles of hay! Certainly, then, a bird on the wing, having to choose amidst myriads of butterflies, may be determined by an almost infinitesimal distinction. Further, though the whole change may be produced by an immense number of small changes, it is not necessary to suppose that all the changes will be equally small. It is merely begging the question to assume that the first change could not possibly be large enough to be of any use. And if it may be of use, the whole mathematical calculation, based on its being useless, breaks down from the beginning. Again, since the *Leptalis* may have spent 1,000,000 years in arriving at its present likeness to the present *Ithomia*, it is impossible to assert that the normal forms of the two butterflies were as wide apart at the beginning of that period as they are at present. The mimicry having once set in, might be retained by parallel variations. This, indeed, cannot fail to be the case, if the protection is to be a lasting one; for when the *Ithomia* varies in outward appearance, unless the *Leptalis* varies in the same direction, the resemblance will be lost. This progressive mimicry would be more valuable than an imitation in which no changes occurred, since the enemies of a mimetic species would in time become aware of a fraud which had no variations at its command, as birds are said now-a-days to pounce without hesitation upon caterpillars which very much resemble twigs. Even "a rough imitation" may be useful in the first instance, and yet when hostile eyes have long been exercised, and have acquired greater and greater sharpness, finally nothing less than *absolute identity* of appearance may be thoroughly effective. Thus the perfecting of the resemblance will be no "mere freak of Nature," nor shall we be "landed in the dilemma that the *last* stages are comparatively useless" in this procedure.

The array of figures brought forward to prove that the *Leptalis* could not have made twenty steps of variation in the direction of the *Ithomia by chance*, would be much to the purpose if any exponent of the theory of Natural Selection had ever argued or supposed that it could. The calculation takes it for granted that the theory is erroneous, instead of proving it to be in error. Upon this assumption, it might have been put far more strongly, only that a stronger way of putting it would have borne on the face of it the suspicion of some inherent fallacy. It begins by supposing that there are "twenty different ways in which a *Leptalis* may vary, only one of these being in the direction ultimately required;" it might quite as truthfully, or even more so, have said a thousand instead of twenty, and then the second step would have given the chance as only one in a million, instead of one in four hundred. But while the theory of Natural Selection speaks of numerous minute useful variations, Mr. Bennett will not allow that combination of terms. Let them be numerous and minute, if you will, he says, but if small they cannot be useful, if useful they cannot be small. He claims to have Mr. Darwin's own word for it, that a large variation would not be permanent, as though Mr. Darwin had said, "living creatures have come to be what they are by successive useful deviations of structure permanently propagated, but no large deviations are permanent, and no small ones are useful." It is quite obvious that in the use of relative terms, such as great and small, Mr. Darwin neither intended to stultify himself nor has done so. A thing may be large enough to be useful without being large as compared with something twenty times its own size; and a man may be said to have a huge brain in a very small body, although the body in solid content far exceeds the brain. When Mr. Darwin says that "Natural Selection always acts with extreme slowness," he does not imply that its steps must therefore be so numerous as to be too small to confer any advantage. This would be a contradiction in terms. But the steps may be exceedingly small notwithstanding, and also sometimes separated by enormous intervals of time from one another.

In introducing his own explanation of things, Mr. Bennett affirms that "resemblances, and resemblances of the most wonderful and perfect kind" in the vegetable kingdom, "are in no sense mimetic or protective." This may be so, but it can hardly be said to be proved. When he speaks of "man's reason" having "assisted him so to modify his body as to adapt himself to the circumstances with which he is surrounded," and suggests that the instinct of animals may have assisted them also to modify their bodies by slow and gradual degrees to the same purpose, it is difficult to imagine the process intended, and still more difficult to see how "the slow and gradual degrees" will escape the rigid test of mathematical calculation which Mr. Bennett has elsewhere applied; for if the steps are great they ought not to be permanent, and if small they ought not to be useful. A theory which makes it possible for a bee to "modify its proboscis" by instinct, or for a man to treat his nose in the same manner by reason, seems harder of digestion than the Darwinian.

THOMAS R. R. STEBBING

Torquay, Nov. 12

MR. BENNETT, in his very able paper read before the British Association at Liverpool, and published in NATURE of the 10th November, calls in question the explanation given by the theory of Natural Selection of the various instances of mimicry found in the animal kingdom.

He bases his argument principally on the fact that the alterations in the early stages being useless to the animal would not be preserved, and that these changes must be very slow.

He assumes that to enable the normal *Leptalis* to imitate a species of *Ithomia*, it may be considered to have gone through at least 1,000 stages, and that no change less than one-fiftieth of the whole alteration effected would be of any use to the insect. He gives us no information as to how he arrives at these figures, and we are left with the idea that they are selected principally because they are what are called "round numbers," and are more easily dealt with in the calculation which he gives us.

Now I think that the number of stages which Mr. Bennett considers it necessary for a *Leptalis* to pass through so as to mimic an *Ithomia* is vastly too great: 1,000 stages means at least 1,000 years.

Let us look at the alteration which frequently takes place in the colouring of a butterfly, possibly in one generation, as shown by varieties of which sometimes only solitary specimens are known, figured in Newman's work on English Butterflies. I need only refer your readers to the figures of varieties of *Apatura iris*, *Epinephele janira*, *Limenitis sibylla*, *Melitœa athalia.* Now can it be contended that it required 1,000 of such stages to effect the alteration?

If any of these variations happened to be useful, there seems no reason for supposing that one stage might not make much more than $\frac{1}{50}$ of the alteration, which Mr. Bennett lays down as being the least which would be useful, and which I agree with him in considering much too small. Why might not one stage make one-fourth or one-sixth of the alteration required?

Mr. Darwin quotes a passage in his work on Natural Selection (page 32) from Sir John Sebright with regard to pigeons, in which he says that it takes three years to produce a given feather, but six years to make a head and beak. If the bony structure of an animal so far above a butterfly can be altered in six years, we surely do not require more than that time to effect an alteration in the colour of a butterfly's wing.

Mr. Bennett states that the early stages of the alteration would be useless to the insect; every one, I think, will grant this, when each stage is only one-thousandth of the whole, but not if it be a much larger quantity. Here again we may observe the instance Mr. Bennett quotes, the mimicry of *Leptalis* to *Ithomia*. *Leptalis* is normally a white insect, and as such, would be more liable to attacks from its persecutors, as shown by Mr. Wallace, while any variation which gave colour to the wing would make the insect less conspicuous, and being useful to it, would be preserved.

That we are quite ignorant of the laws regulating variation is quite true, and that when we do understand them it will throw much light on these questions is undoubted, and that we may probably find in them some additional explanation for many of the facts now accounted for by Natural Selection; and Mr. Bennett does good service in the cause of truth in reminding us of what still has to be done. S. N. CARVALHO, JR.

London, Nov. 17

FOUR years ago I advanced the opinion that Natural Selection is insufficient to explain the "Origin of Species," and that, rather, the origin of the variations of which Natural Selection is said to avail itself must be looked to for this purpose. I may perhaps, therefore, be allowed to say a few words in examination of Mr. Wallace's explanation of this point in last week's NATURE.

One of the objects of Mr. Darwin has been to show that the existence of species as an absolute entity is a mere idea of our minds; that if we could at the same moment look around us in space, and also backwards in time, we should find the organic world connected together as one whole, one great mass of beings extremely closely allied to each other, and distinguishable only by an accumulation of small and perhaps scarcely appreciable differences. A second and closely-connected object has been to show that this great mass of beings has had a common origin from one primeval ancestor (or at most a few ancestors). These two points are the chief ones involved in the "Origin of Species" question, *as it is ordinarily understood;* and if they be borne in mind, it will be seen that the doctrine of "Natural Selection, or the Survival of the Fittest," deals with only a small portion of the numerous problems involved in this great question. I am sure that Mr. Wallace, after having written as he has done about man, that in his case other influences than this survival of the fittest have been at work, may reasonably allow importance to other powers than Natural Selection in the case of other organic beings.

If Mr. Darwin's book had been entitled "The Influence of Natural Selection on the Formation of Species," some misconceptions might, perhaps, have been avoided. Its present title undoubtedly tends to convey the idea that Natural Selection is *per se* the Origin of Species. I believe Mr. Darwin, however, holds no such idea.

The picture above alluded to, of a complicated mass of beings connected together by innumerable gradations, is so different from what we find existing around us, that one of the first questions suggested by it is, where are the connecting links? This first question has never yet been answered to any extent, or with anything like adequacy. The links produced are but few, and not sufficient to bear the great weight attached to them. For at no period of the geological record do we find any traces of the general and intimate connection of beings with one another that Mr. Darwin's views would lead us to look for. The creatures composing the organic world at any one given moment were, so far as the evidence of geology goes, separated from one another by lines of demarcation of similar value to those existing among animals now.

What is wanted to explain the phenomena of various limited and defined species arising from one common ancestor is, then, first, a law, or group of laws, to throw light on the origin of variation and dispersion; and, second, another law or laws to explain the limitation and separation of the varieties so produced. It is quite out of the question to suppose that the theory of Natural Selection does all this. Those, however, who have studied Mr. Spencer's work will be well aware that his theory of evolution may be applied to deal with the question in this its more extended light. And I believe that those who wish well for the survival of Natural Selection will do well to insist on its only being considered in connection with a more extensive doctrine of evolution. This is where I think Mr. Wallace errs in his advocacy.

I will not here allude to the question of mimicry more than to say, that Mr. Wallace has never answered, but rather avoided, the chief difficulties I have advanced against it; and that his theories on the subject are undoubtedly open to the objection that he insists on seeing all the phenomena from the point of view of a natural selectionist, and nothing more. As Mr. Wallace has, however, already discovered that Natural Selection, though applicable to man, is not sufficient, unsupplemented, to account for him, we may hope that he will yet see this with regard to the rest of the organic world. D. SHARP

Thornhill, Dumfriesshire

The Chromosphere

WHILST mapping down, in preparation for the coming eclipse, all the bright lines that have so far been observed and accurately measured in the chromosphere or solar prominences, I was struck with the absence of a faint yellow line, which I have myself several times observed whilst examining the contour of the sun's disc. This line is probably identical with Angström's absorption line 5883·0 (spectre normal du soleil), D″ lying almost midway between D′ and the line in question. There is no danger of mistaking it for the bright yellow line seen in every solar prominence, and lying near Angström 5865·1, since the two yellow lines were seen on each occasion at the same time on the more refrangible side of D″.

I suppose the D‴, mentioned in a late communication from Dr. Young, to be identical with the bright yellow line, for it is most improbable that he could have failed either to see or to record the bright line whilst mentioning the faint one, since the latter, as far at least as I have observed, is never visible unless in company with the former.

The only observation that I can at all identify with my own is that mentioned in NATURE, December 16, 1869, where Mr. Lockyer, speaking of the absorption line, which corresponds to the orange line of the chromosphere, says that Padre Secchi's bright line is less refrangible.

Stonyhurst Observatory S. J. PERRY

From London to Catania

A FEW practical details as to the best way of getting to Sicily, the accommodation to be found there, &c., may be of use to many readers of NATURE who are thinking of going there next month.

We have first the sea passages from London, Southampton, or Liverpool, to Messina or Malta, of which if any be chosen it will probably be that from Southampton to Malta by the P. and O. steamers, which start every Saturday at 2 P.M., and are nine days on the voyage. (Fares 20*l.* and 10*l.*) From Malta there are steamers twice a week to Messina; they touch at Catania when the weather permits them to enter the small harbour, otherwise they go on to Messina, so that passengers for Catania must in that case avail themselves of the railway.

Few probably will wish to go the whole way by sea, the land route therefore by which the Indian mails are now sent will be taken; viz., over the Brenner Pass. The night mails leave Charing Cross at 8.45 P.M., Cannon Street at 8.50 P.M., Victoria and Ludgate Hill at 8.30 P.M., and arrive in Dover in time for the Calais and Ostend boats; the line from Calais to Brussels *may* not be practicable, and so the longer passage to Ostend may be preferred; by going straight on one ought to arrive at Cologne at 4 P.M. the next day (if one goes by Calais one has three hours' rest at Brussels). The day service train, first and second-class, leaves all the stations at 7.40 A.M., and one should arrive at Cologne *via* Ostend at 10.55 P.M. (*via* Calais at 4.50 A.M. next day.) From Verviers to Cologne there are only first-class carriages in this train. The fares to Cologne by Ostend are 3*l.* 8*s.* 10*d.* first, and 2*l.* 9*s.* 5*d.* second-class, by Calais they are 3*s.* or 4*s.* more.

Those who like to go from London to Ostend or to Antwerp *direct* can leave St. Katherine's Wharf by steamer on Sunday, Tuesday, or Thursday mornings for Antwerp, or on Wednesday or Saturday mornings for Ostend, and proceed by rail to Brussels, the fares from London to Brussels being 30*s.* first and 22*s.* 3*d.* second class, *via* Antwerp; 26*s.* 8*d.* first and 20*s.* 10*d.* second class, *via* Ostend. The fare from Brussels to Cologne is about 25 francs first and 18 francs second class by the ordinary trains; express about three francs more.

The way then is by Coblentz, Mayence, Darmstadt, and Aschaffenburg to Munich. By leaving Cologne by the 6 A.M. express, one ought to get to Munich at 9.10 P.M. In times when through-tickets are granted the fare by Ostend and Cologne to Munich is 6*l.* 7*s.* 3*d.* from London (first class), and 5*l.* 10*s.*

mixed first and second; this will give some idea of what the cost will be.

After Munich the regular trains may be relied on; one can leave Munich at 9.50 P.M. (first and second class), pass Innsbruck, and crossing the Brenner in the early morning descend the Italian side in the forenoon, getting to Verona at 1.20 P.M.; or by leaving Munich at 10.15 A.M. (first, second, and third class) one may get to Verona at 5.50 A.M. next day; but in this way one misses the best of the scenery. The fares from Munich to Verona are about 37*s*., 25*s*., and 18*s*.

The way, then, is to Padua, Bologna, Pistoia, and so either to Florence or to Leghorn (by Pisa); from Florence to Rome, passing by Lake Trasimene; from Leghorn to Rome by the coast line, or else straight to Messina or to Naples, and then to Messina, by one of Rubattino's boats, which leave almost daily. From Rome one goes to Naples by train, and thence by boat to Messina, passing close to Stromboli. Some of the boats go on to Catania, but it is advisable to land at Messina and take the train, as often the steamer cannot get into the harbour at Catania, in which case it goes on to Malta. The railway fares from Verona to Naples come to about £4 10*s*. first; £3 5*s*. second; and £2 5*s*. third class.

By travelling *almost incessantly* one should (supposing the trains regular) get to Naples from London in five days and six nights by this route: no time is lost by spending a night at Cologne.

At Messina, the Custom House authorities are usually rather troublesome, but one does get off at last, and, passing along a most exquisite coast-line, arrives at Catania (Κατ' Αἴτνῃ).

The hotel at which to stay, if possible, is the Grande Albergo, kept by Herr Werdenberg, where there is every comfort, the very small salon being redeemed by the fine billiard-room. The front rooms face towards the north, and are cold and unsuited for invalids, but they (especially those of the third story) afford a most splendid view of Etna, the sunrises and sunsets seen from them being superb. The rooms at the back are much warmer, but of course give no sight of Mongibello. The Grand Hôtel Central is an Italian establishment in the Piazza dell' Università, and may be considered to be the second, though much inferior to the first-mentioned house.

In Catania itself a good post of observation would probably be the Giardino Bellini on the Corso; it is high and sufficiently large.

To go to Nicolosi a two or three-horse carriage is necessary. There are at this village two inns, one at the entrance to the village (not to be recommended), the other one, which is preferable, farther on in the village. The accommodation is of a very primitive description. Everything should be taken from Catania, as little can be got at Nicolosi.

From Nicolosi one can visit the Monti Rossi (in half-an-hour or three-quarters), from which one has a magnificent view, and one can, if one is curious enough, go down into a hole, known as the Fosse dei Palumi, a volcanic vent.

It is from Nicolosi that the ascent of Etna is made, and a description of an ascent, under especially favourable circumstances, will be found in the number of NATURE for June 23 last.

The best guide is Pietro Cravagna, who knows the mountain thoroughly, and who also speaks tolerable Italian; he is in every way to be trusted, and if another guide be necessary, it will be well to let Pietro find him. The writer was on one occasion subjected to great annoyance from the incompetence of one of the so-called guides.

The Casa del Bosco, about two-and-a-half-hours' ride from Nicolosi, is uninhabited during the winter. A fire of sticks may be made there, and a few plates, &c., will be found; the key must be got at Nicolosi; there is plenty of good water close at hand. This house might be used for purposes of observation; it has two rooms, and an outhouse for the mules.

The Casa degli Inglesi, near the top of Etna, is almost sure to be buried in the snow.

In descending from the summit it may perhaps be possible to go down into the Valle del Bove, and return to Catania by Zaffarana. Those who visit Sicily should not return home without stopping a day or so at Taormena (between Catania and Messina), and seeing a sunrise from the ruins of the theatre.

W. H. C.

The Spectrum of the Aurora

As some of your correspondents seem scarcely aware of what has already been accomplished in observation of the auroral spectrum, perhaps I may be pardoned a few remarks on the subject.

The line usually most prominent in the auroral spectrum is a yellowish green one, the wave-length of which was measured by Angström as 556·7, and its position by Professor Winlock as 1280 on Huggins' scale, which, reduced to wave-length, closely agrees with the determination of Angström.

Angström also observed the same line in the spectrum of the zodiacal light, in March 1867, but it seems possible it might be due to faint aurora concealed by the light. He says that "it is a remarkable fact that this bright band does not coincide with any of the known rays of simple or compound gases which I have as yet examined." The wave-length of H β is about 486·2; much less than that of the auroral line. Angström also saw three very feeble bands near H β (F).

Professor Winlock (*American Journal of Science*, Nov. 1869,) states that in addition to the line at 1280 Huggins' scale, he saw six faint bands, viz,, at 1400, 1550, 1680, near F, 2640, and near G.

In the *American Journal of Science*, Sept. 1869, it is stated that during the solar eclipse a bright line was seen in the spectrum of the corona at 1474 of Kirchoff's scale, and that it coincided with an auroral line. 1474 Kirchoff corresponds to about 1550 Huggins' scale.

I have also somewhere seen it stated that the auroral line at 1280 coincided with a telluric line in the sun's spectrum, which might be possibly due to oxygen.

I have myself seen several feeble bands between the green line and F, but owing to their faintness have not yet been able to determine their position with much accuracy.

The red line which was so bright in the aurora of the 24th and 25th ult. is only occasionally visible. Mr. T. W. Backhouse has observed it repeatedly, and informs me that it is sometimes visible when the aurora does not appear red to the eye, but that he never recollects seeing it when some part of the sky was not red. This quite agrees with my own experience. As your correspondent, "T. F." observes, the red line probably belongs to a spectrum distinct from that of the green line, and may be due to some other gas. It may, however, be only a fresh line of the same gas due to different temperature. Its position from repeated direct comparison is about ·4 of the distance from Hα, to Na. as I stated a week or two since. It is, therefore, not identical with Hα, to which the ordinary red light of ignited hydrogen is due.

Changes of pressure and temperature do not affect the *position* of lines, but merely influence their breadth and intensity, making new lines visible and expanding old ones. Sometimes, as in the well-known case of nitrogen, an entirely fresh spectrum is produced; but while any line remains visible its position is unchanged. Hydrogen gives several such spectra, but I believe none of them have a line in the position of the auroral one.

I am at present engaged in a little research on the spectra of certain gases in relation to that of the aurora; but it is not yet sufficiently advanced for publication.

It is particularly desirable that the positions of lines should be accurately determined. In the case of the aurora I am acquainted with no better method for doing this than by comparison with such a spectrum as the band spectrum of N. This is a most convenient natural scale, with thirty or forty brilliant bands; and may readily be obtained from a small tube containing rarefied air or nitrogen, by the aid even of a Ruhmkorff's smallest coil.

With regard to the spectroscope, a simple flint glass prism fitted to a tube carrying an adjustable slit, and without any lenses, gives a brighter spectrum than any other form of instrument that I am acquainted with.

HENRY R. PROCTER

Clementhorpe, North Shields, November 12

The November Meteors

ON the nights of the 12th, 13th, and 14th of November the sky was constantly watched from 5 P.M. to 7.30 A.M. The weather throughout was most unfavourable.

On Nov. 12th it was completely overcast from 7 P.M. to 7.30 A.M.

On the 13th from 5 P.M. to 7 P.M. the amount of cloud was $\frac{7}{10}$, and only one meteor was seen. The sky was then obscure until near 1 A.M. of the morning of the 14th.

Nov. 14th, from 1 A.M. to 3.50 A.M., the amount of cloud was $\frac{7}{10}$, and four meteors were seen, two starting from near γ Leonis.

This was preceded by a hailstorm and rain, with occasional breaks in the clouds, through which we observed four meteors between 5 and 6.30 A.M.

On the evening of the 14th the sky was only half covered with clouds from 5 to 8 P.M., and eight meteors were observed between 5.48 and 6.40; one at 6.2 was of a brilliant red colour, with a pale greenish white train.

From 7.40 to 8.35 five other meteors were seen. The sky cleared for a short time towards 8 P.M., but at 9 a mist came on which obscured the heavens during the remainder of the night, clearing off, however, occasionally for a short time. I will not trouble you with the path of each separate meteor, though each was carefully noted. From the above observations I should be inclined to think that we had passed through the maximum during the afternoon of the 14th. Had there been any brilliant display during the night of the 14th, I think it would hardly have escaped me in spite of the mist.

Stonyhurst Observatory S. J. PERRY

SPAIN AND THE ECLIPSE EXPEDITION

THE following is a translation of a letter which appears in the *Astronomische Nachrichten* for Nov. 15, on the facilities offered by the Spanish Government to such foreign astronomers as purpose visiting Spain on the occasion of the approaching eclipse :—

"MADRID, *Nov.* 5.

"I have the honour to inform you that the Spanish Government, at the request of the Observatory at Madrid, and in accordance with the resolution taken at the time of the eclipse of the sun in 1860, has just agreed that similar measures shall be adopted for facilitating to foreign astronomers the observation of the approaching solar eclipse on the 22nd of December of the present year. The Government has in consequence resolved,—

"'That at the Spanish Custom Houses no duty or deposit shall be demanded on the astronomical or physical instruments that astronomers bring into Spain for the observation and study of the eclipse.'

"But as this privilege, which has been granted with readiness to astronomers, might be taken advantage of by persons noways connected with Science, the Government has deemed it necessary to adopt certain measures of precaution, the principal one of which is, to be made cognisant of the names of the persons who are making preparations to come to Spain to observe the eclipse. In consequence thereof, the Minister of Finance has directed 'that such astronomers as purpose availing themselves of the resolution above spoken of should have the goodness to make known in writing to the Observatory at Madrid their names, the number and the class of instruments which they bring, and the point of the coast or frontier where they purpose entering Spain.' These particulars will be communicated by the Observatory to the Government, which will send orders to the Customhouses to pass without difficulty all the instruments entered on the lists the astronomers furnish. Foreign astronomers may, moreover, reckon on the sedulous protection of the provincial governors and of the local authorities, from whom they will receive all the co-operation necessary to enable them to devote themselves with entire liberty to their scientific labours.

"In the Almanac of the Observatory of Madrid for 1870 (which you have not received owing to the want of communication with Germany for several months) there is contained a somewhat detailed account of the approaching eclipse, accompanied by two maps. As you will observe, in the zone of the total eclipse there have been inserted all the principal towns, in order to assist astronomers in the selection of their stations for observing. This central line is not of great dimensions in Spain (about sixty nautical miles) yet, nevertheless, there are numerous important towns in proximity to the central line, as, for instance, San Lucar, Jerez, Puerto de Santa Maria, Puerto Real, San Fernando, Cadiz, Medina Sidonia, Estepona, and at those places observers will meet with all the resources requisite for carrying out their labours with facility. The sole disadvantage of so short a line is, that if the weather should prove unpropitious at one station, it will probably be so at the others as well

"If you think any further details necessary, or in the case of any astronomer wishing to consult the map of the eclipse, nothing more will be necessary than to apply to the Director of the Observatory at Madrid, who tenders his services to such foreign astronomers as require them, and to whom it will afford great pleasure to aid his colleagues in bringing their scientific mission to Spain to a successful result. ANTONIO AGUILAR"

THE CONSTRUCTION OF HEAVY ARTILLERY

IN few other manufactures has it been found necessary to search so deeply into the materials nature provides in order to find out the best and strongest, and then to apply it skilfully, so as fully to develop its strength, as in the manufacture of guns. The construction of the amazingly-powerful ordnance which modern naval warfare employs is pre-eminently a question of strength of material; indeed, it may be termed *the* question of strength of material. In nothing else does man employ forces even nearly so powerful and violent. The force of steam, even when doing its mightiest work, is but faint and small compared with that of the exploding charge of gunpowder that sends from the gun a 300lb. or 600lb. shot with a velocity which carries it through thick armour plates of wrought iron. A 600lb. shot will pierce twelve inches of iron at 200 yards distance. This gigantic force is imparted to the shot in the brief fraction of a second that it is moving down the barrel of the gun. Remembering that "the gain in power is loss in time," and consequently that when the time is diminished the power is proportionately increased, we may form some conception how enormously great is that force which is exerted within the breech of a heavy gun, and which is resisted by it every time it is fired. It is a force which, if turned into foot pounds, would represent the steam power not of a ship but of a navy. Yet all its work is to be done in the space of a few inches, and it must be surrounded with iron strong enough to resist it. Here we have the skill of man grappling with enormous difficulties, searching out the strongest and most suitable material that nature supplies, and exerting all his art to apply it to the utmost advantage. The construction of these exceedingly powerful guns has been entirely developed within the last few years. The gun now manufactured in Woolwich Arsenal is more unlike the gun of 1850 than the gun of 1850 is unlike that of Queen Elizabeth's reign. The progress of twenty years surpasses that of three centuries. And the change has not been so much in enlargement of size as in difference of construction. Queen Elizabeth's pocket-pistol is not more unlike a 600-pounder in external appearance than in internal structure. The gun which is carried in the turret of one of our ironclads, and which, at a single discharge, expends as great a weight of powder and shot as the whole broadside of a good-sized frigate of our own early days, does not surpass the gun which peeped from that frigate's ports so much in size and power as in the superior scientific principles of its manufacture. We propose in the present article to give a general view of these principles. The method of manufacture will be first explained, and afterwards the principles which guide the selection of the best material. Although the material must be selected before it is manufactured, yet a knowledge of the construction of a heavy gun, and of the qualities sought by construction to be developed, will very greatly facilitate our comprehension of the reasons of choice and preference among the many kinds of iron that might be and that are used.

In explaining the construction of modern ordnance as made for the British Government, it will be best to notice the gradual progress in the manufacture since wrought-iron began to be used instead of cast-iron. This was the first great change, and from it dates a new era in this branch of industry. And it was not only a great change, but a great advance. Wrought iron is a very much superior material to cast-iron, and one which demands very much more skill in its manufacture. Cast-iron is of a granular or crystalline nature; wrought-iron is fibrous: cast-iron is hard; wrought-iron tough. The difference between them may be illustrated by the difference between glass and wood. One is strong to resist a statical strain or pressure, the other to resist a dynamical strain or blow. There is a vast difference between the two kinds of strength. A brick which is at the foundation of a lofty factory chimney supports an enormous weight, but it would be broken by a blow that would not injure a stout walking-stick. Wrought-iron having that kind of strength which resists dynamic force

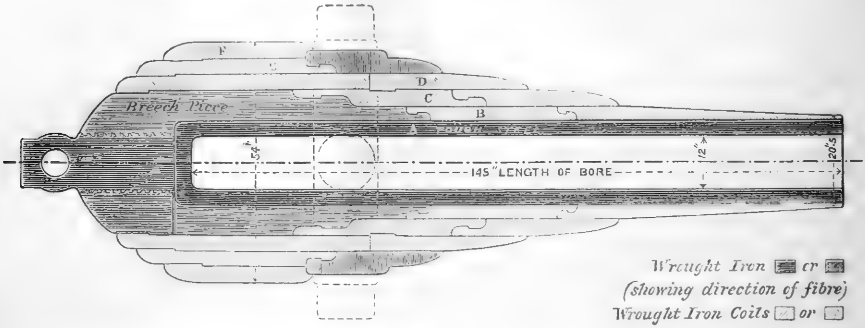

FIG. 1

is therefore far preferable to cast-iron for resisting the violent and sudden shock of explosives, the most powerful dynamic strain with which man's art has to grapple. It averages three times the dynamic strength of cast-iron, that is, it will bear three times as great weight without breaking. It will yield sooner; but when cast-iron yields it breaks. In this another great advantage is gained. When a cast-iron gun breaks it does so explosively; it breaks up into fragments, and gives no warning, no indications of yielding beforehand. But a wrought-iron gun shows when its use is becoming dangerous.

Though this discussion seems rather at variance with the plan laid down, yet it is necessary to have a general knowledge of the material used in order to understand the method of manufacture. Wrought-iron, while it is so much better a material for the construction of heavy

Scale 3/8" = 1 Foot.

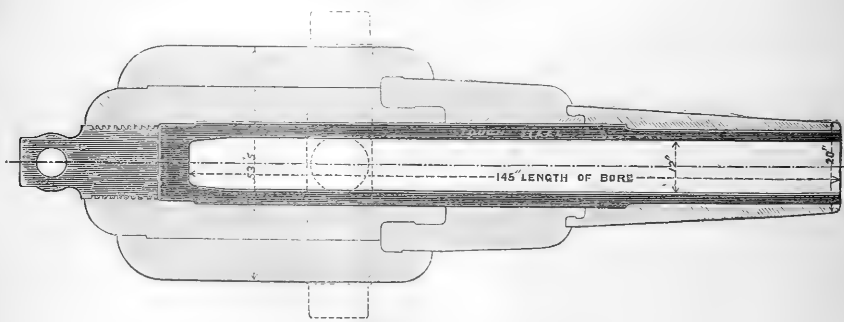

FIG. 2

guns, is yet very difficult and expensive to work. The wrought-iron gun cannot be made as easily as the gun for which the molten metal was run into a mould and then bored out and finished exteriorly. It requires large furnaces, huge steam-hammers, and skilled workmen to give it shape. Before the wonderful appliances of modern science and machinery were invented, wrought-iron could only be made and worked in comparatively small quantities. And even now to forge the mass necessary for a gun 7, 12, or 25 tons weight, would be a most difficult and costly, perhaps in the last case an impossible undertaking. No doubt there are larger forgings used in large steam ships for cranks and shafts, and in other machinery; but these masses of wrought-iron are not heated and hammered the whole at once. Separate parts are welded together, or successive portions are heated and hammered. It is needless to say that these methods would not do for the construction of a gun. The fiercely expanding gas of the exploding powder would speedily and fatally detect any plane or point of weakness. Moreover, wrought-iron is not equally strong in all directions; being fibrous in its texture, it is twice as strong with the grain as across the grain. As in the case of wood, which it is much more easy to split than to break, so it is much easier to tear the fibres of wrought-iron from each other than to break them across. It therefore follows that a gun forged in a solid mass, and bored out, would not put the strength of wrought-iron at its greatest advantage. Such a gun would be very strong along its longitudinal section, very strong to resist the strain of the gunpowder to tear out the breach; but it would be only half as strong in its transverse or cross section to resist what may be specially termed the bursting strain. These difficulties were entirely overcome by Sir William Armstrong's system of making a gun of coils of wrought iron bars. By that the difficulty of forging a large mass is altogether put away; and the fibre of the iron passing round the bore of the gun instead of along it, gives the greatest possible resistance to the bursting strain of the powder's explosion. This was a very great advance, a most valuable improvement in the manufacture. It took away the difficulty and expense which were the great obstacles to constructing ordnance of wrought-iron, and at the same time applied it in such a manner as to increase, or rather put at the utmost advantage, its strength in resisting the transverse or bursting strain of the powder's explosion, which is the most difficult and important strain to overcome. It is for this last that this invention deserves its highest praise; for gun-making is above all a question of strength of material. The best material applied in the best way is hardly strong enough to resist the enormous charges behind the enormous shot which are required to pierce the armour-plated vessels of modern warfare.

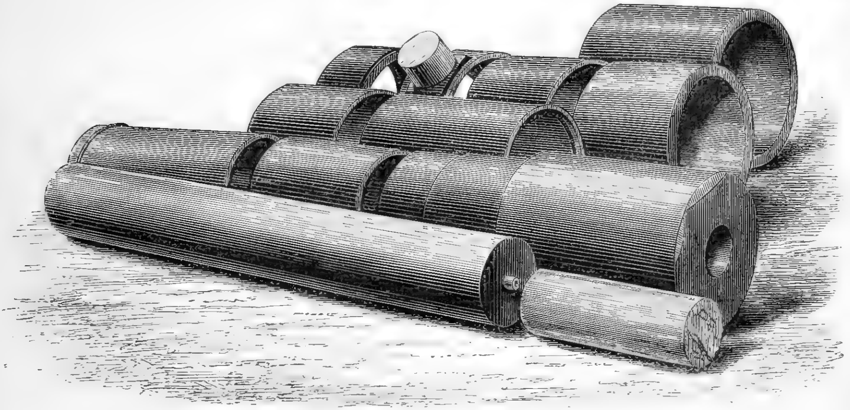

FIG. 3

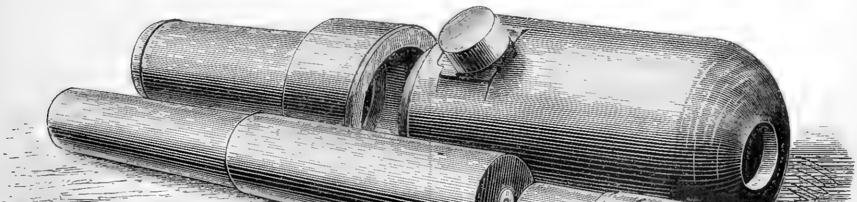

FIG.

The method of making the coils is as follows: A long bar of iron is heated to nearly a white heat in a long low furnace, and when thus rendered soft, it is hooked on to the side of what resembles a gigantic reel of iron. This reel or core is then turned by machinery, and the glowing bar is wound upon it; being drawn from the furnace upon a travelling groove, which, aided by blows on the bar from a heavy hammer suspended above and guided sometimes by two men, keeps the bar in its proper position as it is coiled. When that is completed, it is removed from before the furnace, the reel or core taken out, and the coil allowed to cool. Afterwards it is heated in a reverberatory furnace, and welded together by blows on the ends from a steam-hammer; the edges of the coiled bar are melting from heat, and therefore unite when thus forcibly pressed on each other, so that it forms a complete hollow cylinder or tube of wrought-iron, the fibre going round the circumference. The rough surfaces are afterwards turned off in powerful lathes. These coils are made of various sizes, and several of them are required for each gun. They are *shrunk on*, that is, the outer ones are not quite large enough to go over the inner ones, but are heated, and when thus expanded are placed over their smaller brethren, whom, as they cool, they clasp in a tight embrace. Thus all the coils are in a state of tension inwards, and this was supposed to increase their power of resisting the shock of the discharge which came from within outwards. However, this theory very decidedly admits of question. Even a little observation seem sufficient to show that anything in a state of tension is thereby weakened to resist a shock in any direction. A shock produces a kind of undulation or vibratory action, so that its effect returns back in the direction in which it was imparted. In Sir Joseph Whitworth's guns the hoops were made accurately to fit each other, so that no shrinking was required; but a little shrinkage, we believe, was used to ensure close fitting. It will be seen further on that this question of the advisability of shrinkage does not apply to the guns now made for the British service. Hitherto we have only spoken of coils, which, though a main part and distinctive feature of the Armstrong gun are not the whole of it. A gun made altogether of coils would lack strength in resisting the longitudinal strain, or tendency of the discharge to tear out the breech endways, and this would be an awkward event for the gunners, if the gun fired, so to speak, at both ends. To prevent this, Sir William Armstrong had a large forged piece of iron, like a great cap, placed on the breech end of the inner tube and under the coils. The fibres of this, running longitudinally, made it strong in that direction, and guarded against a catastrophe so much to be dreaded. This, however, was a large forging, and therefore very expensive; and, also, while it strengthened the gun longitudinally, it weakened it transversely, by taking up the space nearest the bore where the greatest part of the strain was sustained, and filling it with iron whose fibres were in the direction of the bore instead of around it, as those of the coils. It is easy to see how much this took from the power of the coils to resist the lateral, transverse, or bursting strain of the discharge. The force which the expanding gas exerts on the material of the gun must necessarily be inversely as the square of the distance from the centre of the bore. A coil removed from the tube by the thickness of the forged breech-piece cannot resist the full strain of the explosion nearly so effectively as if it came at once round the tube. Its strength is applied at a disadvantage represented by the ratio of the square of the radius of the coil round the forged breech-piece to the square of the radius of a coil round the inner tube.

Besides, there is another large forging in the Armstrong gun, the trunnion-piece, which is placed round the middle, and carries the trunnions or short arms by which the gun rests on its carriage.

An Armstrong gun may be thus summed up. (The section of a 600-pounder is shown in Fig. 1 as an example.) First there is a tube of steel (A); this metal is always used for the inner part, as its hardness and closeness of grain make it better adapted for the rifling—the grooves would be quickly worn by the friction of the studs of the shot in softer metal—and also better to resist the action of the violently expanding gas of the exploding charge of powder. All attempts to make the inner tube of coils were unsuccessful; the gas at its enormous pressure searched out and took advantage of the most microscopic flaws. Next comes the large forged breech-piece behind the steel tube, and extending some distance along it. Then come the coils (in 5 sets, B, C, D, E, F), shrunk on one over another. And lastly, the trunnion piece round the middle.

The Armstrong gun, as described in our former paper, was the pattern on which all our guns were made for the British service till 1866, when very important changes, which had been proposed by R. S. Fraser, member of the Institute for Civil Engineers, and Deputy-Assistant-Superintendent of the Royal Gun Factories, after a prolonged series of trials, were approved and adopted by Government. This gentleman, not long before, introduced into the manufacture of ordnance a cheaper, and, at the same time, a better kind of wrought-iron than that before used, and he has imported into the construction of the Armstrong gun very considerable modifications, by which the country is provided with a stronger gun, one-third cheaper, and more quickly made.

These are three very important items of improvement; viz. strength, cheapness, and rapidity, because simplicity, of manufacture. The saving effected is from 35 to 40 per cent. on the vast sums expended on heavy ordnance. Most of our readers have heard of the Fraser gun, but few, perhaps, know where or how it differs from the original Armstrong gun, although all our heavy ordnance is now made on this pattern. The information, therefore, may be not uninteresting, and a comparison of Fig. 2 with Fig. 1 will help to make the difference clearer. Instead of the forged breech-piece, the many small coils, and the forged trunnion-piece that form the Armstrong gun over the inner steel tube, Mr. Fraser uses one immense coil, of which the trunnions are part, and which is closed behind the tube by a large screw forming the cascable, and which is the only forging used in his gun. This will show at once how the economy is effected. Both the large forgings of the Armstrong gun, the breech-piece, and the trunnion-piece are got rid of; and instead of having many coils to be turned, and have their inner and outer surfaces reduced, upon which labour and time were expended, in addition to the waste of metal, there are only the two surfaces of the one great coil to be turned. In the 600-pounder, on the old principle, there were sixteen coils, and twice that number of surfaces, each representing labour and loss. For these reasons also the guns may be made much more quickly. This is a very important advantage, as in an emergency the country could be more quickly armed. Strength is also gained to resist the transverse strain in two ways, because the coiled iron comes next the steel tube, where the forged breech-piece used to come formerly, and so the coils are applied at greater advantage, and secondly, because the one thick coil is stronger than several thin coils, just as a triple deal is stronger than three inch deals. And further, the gun is stronger to resist the longitudinal strains, because the breech and trunnions are all of one piece, and so the force of the discharge upon the gun acts through the trunnions on the carriage, and has not, as in the old pattern, a tendency to destroy it by tearing one piece or part of the gun from another. It is converted from a longitudinal bursting strain into recoil.

It only remains to describe how this immense coil, which is the marked feature of the Fraser gun, is made. A long and thick bar, much thicker than the one used in the Armstrong pattern, is heated and coiled in the manner before described. When this has cooled, another bar, somewhat longer, is coiled upon it in an opposite direction, that is, if the first coils go from right to left, the second go over them from left to right, just as the boa constrictor overlaps his coils on the prey which he is crushing. And then a third bar is coiled in the same direction as the first. The whole is then heated in a large reverberatory furnace, and a few blows from a powerful hammer weld them into a thoroughly combined mass.

This principle of construction seems to apply the iron to the utmost possible advantage in resisting the force of the exploding charge. There is an eloquent testimony to the excellence of the system in one of the first guns made on the Fraser principle, which was tested to destruction in the preliminary trials that took place before the system was adopted, and is now to be seen in the *cemetery*, or place where such guns are preserved for inspection in the Royal Arsenal. This gun, a 64-pounder, having fired a greater weight of powder and shot than any other of its own size, and latterly with charges increased till it was destroyed, burst in this way: part of the tube, which was worn through, and the coil round the front of the tube came out and left the entire mass of the trunnion and breech-piece uninjured, so that not only would this bursting have done no injury to those who served the gun, but if a new tube and fore-part were put in, the trial might have commenced again.

Welding a coil, however large, is a much easier and less expensive process than forging and hammering into shape a mass of iron of much smaller size. However, the great size of the coils of Fraser guns of large calibre necessitated the employment of correspondingly large furnaces and machinery. These difficulties have been very successfully overcome in the Royal Gun Factories. The furnaces have been enlarged from a cubical content of 60 feet to 600 feet. At present a gun is being made of 35 tons weight, which will hurl a shot of 700lb. weight with a charge of 120lb. of powder (the battering charge for the ordinary 25-ton 600-pounder being 70lb.) All the coils for this enormous weapon have been welded without accident or hindrance. In one case as much as 28 tons of iron have been heated in one piece in the furnace, seized by the tongs, and placed in a glowing mass beneath the hammer. This is an achievement unprecedented in iron manufacture, and which reflects the highest credit on this most important Government department. Nowhere else, and for no other purpose, have such gigantic masses of metal to be heated and manipulated.

Figs. 3 and 4 show the parts of an Armstrong gun, and of a Fraser gun, before they are put together. Both are 300-pounders, and the engravings have been made from photographs of the actual guns.

NOTES

We are in a position to state that the arrangements of the Eclipse Expedition are rapidly progressing,—thanks to the untiring labours of the strong Organising Committee, which meets almost daily. As we stated before, the Government are bringing all their power to bear in favour of the work, and, should the weather be favourable, we may expect such a series of observations as has never been made of an eclipsed sun. As at present arranged, there will be four parties. Beginning with Spain, we have one to Cadiz, in charge of the Rev. S. J. Perry, and one to Gibraltar, under Captain Noble. The English branch of the Anglo-American Expedition will be under the charge of Mr. Lockyer; while there will be a fourth small expedition, under the charge of Mr. Huggins, to Oran; the Cadiz, Gibraltar, and Oran parties will leave Portsmouth on the 5th of December in the *Urgent*. The Sicilian party will leave London on the night of the 7th by the Brenner pass, a ship of war meeting them at Naples. Although not a single official astronomer has olunteered to go, there will be lack of neither skill, discipline, nor organisation; and arrangements are already being made which will ensure a full and early publication by the Organising Committee of the scientific results obtained. Printed instructions are being prepared by the Committee for each class of observations. So much for the English Government Expedition. With regard to the American one, we may add that it has been no less strongly and carefully organised, with the distinct advantages that astronomy is more cultivated in America than it is here, that the official observatories are fully represented, and that as all the observers were present at the Eclipse in 1869, they therefore may be regarded as veterans. Professors Young, Pickering, Newcomb, Peters, Watson, Harkness, and others are at present in London, and are daily affording most valuable information to the Organising Committee and the various observers.

The following memorial to Her Majesty's Government on the danger to which the scientific, literary, and art collections of Paris are now exposed, has been forwarded to the Earl of Granville from the University of Dublin:—"We, the undersigned, Provost, Fellows, and Scholars of Trinity College, and Professors of the University of Dublin, desire to express our satisfaction with the efforts made by Her Majesty's Government to restore peace in Europe, and our earnest hope—shared, we believe, by the nation at large—that these efforts may be eventually successful. But if, unhappily, our desire should not be realised, your memorialists venture to urge that the interposition of Her Majesty's Government may be directed to preserve, if possible, the great scientific, literary, and art collections of Paris, which are, in truth, the property of the whole civilised world. It is impossible to contemplate calmly the irreparable loss which the destruction of these collections, or even any serious injury to them, would inflict upon students of every nation. To avert, if possible, such a calamity, is now the duty of all; it is more especially the duty of every scientific and literary institution. Your memorialists would, therefore, in the name of our ancient University, earnestly entreat Her Majesty's Government to interpose their good offices with the belligerents, for the purpose of saving these matchless treasures from a danger which the fate of the Library of Strasburg proves to be only too real."

We understand that Dr. Neil Arnott, in addition to his recent munificent donations to the Universities, has just presented 500*l.* to the Aberdeen Mechanics' Institution, to aid in maintaining lectures in Physical Science.

At the examination for Foundation Scholarships, held in the week after Easter, 1871, one or more scholarships will be obtainable by proficiency in the Natural Sciences, at Trinity College, Cambridge. Should one scholarship only be so assigned, preference will be given to the candidate who shows the greatest proficiency in physiology and the allied subjects. The Examination in the Natural Sciences is open to all undergraduate members o the Universities of Oxford and Cambridge. The value of the scholarship is about 80*l.* per annum for five or six years.

Dr. Michael Foster (the newly-appointed Prælector of Physiology at Trinity College, Cambridge) commenced on the 14th inst. his course of lectures in a part of the new museums, which has been temporarily fitted up as a Physiological Laboratory. He gave a lucid and able exposition of the three great factors of life—contractility, as evinced chiefly in muscles; irritability, as evinced chiefly in the nervous system; and secretion. Dilating upon the much-vexed question, how far these are attributable to physical agencies, or are to be referred to another agency called "Life," he compared the latter view to a fortress closely besieged by an able band of investigators who are ever narrowing its area, and pressing the physical forces closer and closer upon it. But it has not yet capitulated. No one has a right to say that it will or will not capitulate; and till it has done so we are perfectly justified in regarding it as an entity, as a something to be taken into account in the investigation and the attempts at the explanation of living processes. He should still, therefore, use the term without committing himself to either view. He gave definitions of Physiology and Morphology. He spoke of the enormous importance of vivisection to the advance of Physiology. By it Vesalius might be said to have laid the foundations of Physiology; by it Harvey had been enabled to obtain the proofs of his great discovery. Without it all that had been written on Physiology would have gone for very little, and we should still have been in the Aristotelean mists darkened by the theories of the Schoolmen. He wished, however, to state that in the teaching of Physiology it would be necessary for him to resort to it much. He stated the plan he intended to pursue in carrying out the intentions of those who had placed him in that honourable position. Lectures he did not regard as a very fructifying mode of sowing seed. He thought it far better that men should work and see for themselves. With the munificent aid of Trinity College, he hoped, ere long, to make the physiological laboratory in Cambridge one of the best working laboratories in the country. He intended to have practical classes in addition to the lectures; and students who were competent would have opportunities for private work. It would be a labour of love to him to render practical aid to those who needed it, and to promote the study of physiology by every means in his power.—A considerable number of the senior members of the University were present, as well as undergraduates, and warmly applauded at the close of the lecture. The lectures are for the present open to all members of the University without fee.

AT the recent examination for the Natural and Experimental Science Moderatorship at Trinity College, Dublin, Gold Medals were awarded to R. Apjohn, W. F. Burton, and T. F. Fleetwood (*Sch.*), and a Silver Medal to R. Barrington. The subjects examined in were—1. Physics; 2. Chemistry; 3. Mineralogy and Geology; 4. Palæontology, Zoology, and Botany. No candidate was allowed to present himself for examination in more than two of the four branches.

REV. PROF. HAUGHTON, M.D., F.R.S., has commenced a course of Lectures in Trinity College, Dublin, on Physical Geology, and Prof. Macalister, M.D., a course on the Anatomy, Physiology, and Classification of the Mollusca.

BY the resignation of Mr. J. J. Bennett, the office of Keeper of the Botanical Collections at the British Museum is now vacant. The appointment rests actually with three only of the trustees, the Archbishop of Canterbury, the Lord Chancellor, and the Speaker of the House of Commons, by virtue of their offices. Among the whole body of the trustees, who would naturally be consulted, there are only four scientific men, the President of the Royal Society, Sir R. J. Murchison, Lord Enniskillen, and Sir Philip Grey Egerton. Now that we are about to remove our national collections to a new building erected for the purpose, the suggestion naturally arises whether this is a condition of things which is desirable to perpetuate. The whole subject of the mode of appointments to these Government offices is one well worthy of the consideration of the Royal Science Commission. Mr. Bennett entered the Museum in 1829 as assistant, and succeeded the late Robert Brown as Keeper at his death in 1858. Mr. W. Carruthers, the present senior assistant, on whom the appointment would naturally fall, and who is so well known for his researches in vegetable palæontology, entered on that office in 1859.

THE first course of Cantor Lectures of the Society of Arts for the ensuing Session will be "On Artists' Colours and Pigments," by Frederick S. Barff, M.A., F.C.S., and Fellow of the Cambridge Philosophical Society. It will consist of five lectures, to be delivered on Monday evenings, the 21st and 28th November, and the 5th, 12th, and 19th December, at eight o'clock. These lectures will treat of—the Nature of Colour; Chemistry and Manufacture of Colours and Pigments; Vehicles and Media used in Painting; Fresco and Silicious Painting; Destructive Influences on Colours, &c. Other courses of lectures are under arrangement for delivery during the Session. These lectures are open to members, each of whom has the privilege of introducing two friends to each lecture.

THE *Gardener's Chronicle* states that an interesting exhibition of fruit has been recently opened at Appenzell, Switzerland. Eight communes have furnished 689 exhibits, comprising 80 sorts of apples and 120 of pears. The fruits are arranged according to the height above the sea of the localities where they are grown. Thus, in the lowest zone are shown fruits which have been produced from 1,300 to 2,000 feet above the sea; in the next, those grown at an elevation of 2,000 to 2,600 feet; in the third group, those gathered at a height of 2,600 to 3,000 feet; and lastly, are exhibited fruits produced above the last-mentioned elevation. Great care has been taken to ensure the accurate nomenclature of the fruits exhibited.

A REMARKABLY low wave of temperature passed over these islands in the middle of this month. At Blackheath the mean temperature for the week ending Nov. 16 was nearly 7° below the average. It is remarkable that the wind was in the W.S.W. during nearly the whole of the week, the air being almost saturated with moisture, and yet the rainfall scarcely appreciable, 0·04 in. For the fourteen stations in England, eight in Scotland, and one in Ireland, recorded by Mr. Glaisher in the *Gardener's Chronicle*, the lowest minimum was 19·0° at Paisley, the highest, 31·5°, at Norwich. The mean temperature was nearly the same in Scotland as in England, about 37·5°. Another singular meteorological phenomenon occurred this week in the successive thunderstorms which burst over London from 3 A.M. on Tuesday morning the 22nd to 6 A.M. on Wednesday morning the 23rd. The wind was blowing strongly from the S.W. during the whole time, with occasional violent rain, and the average temperature was about 40° F.

THE Address on Medicine at the annual meeting of the British Medical Association will be delivered by Dr. George Johnson, and that in Surgery by Prof. Lister.

THE current number of *Fraser's Magazine* contains the first portion of a paper on "Mystic Trees and Flowers," which will interest those who have paid any attention to the subject of Tree-worship, with regard to the origin of which no clear theory has yet been proposed. The writer considers that the religious homage paid to trees "must be referred to a distinct religious phase in the development of races, and to a period later than the ideals and myths with which poets invested them." The legends and superstitions of all countries are brought together, showing the points of convergence of the great religions of ancient races; and the connection of the folk-lore of the present day with its prototypes in all ages and in all nations. Reference is made to the recent researches into the history of the popular tales of different countries, and the whole paper teems with suggestive facts. The principal trees dwelt upon in this instalment are the apple, oak, ash, lime, willow, palm, elder, and juniper.

THE *Engineer* states that when the Russian American telegraph is completed the following feat will be possible. A telegram from Alaska for New York, leaving Sitka, say at 6.40 on Monday morning, would be received at Nicoleaf, Siberia, at six minutes past one on Tuesday morning; at St. Petersburgh, Russia, at three minutes past six on Monday evening; at London twenty-two minutes past four on Monday afternoon; and at New York at forty-six minutes past eleven on Monday forenoon. Thus, allowing twenty minutes for each re-transmission, a message may start on the morning of one day, to be received and transmitted the next day, again received and sent on the afternoon of the day it starts, and finally reaches its destination on the forenoon of the first day, the whole taking place in one hour's time.

FOR the purpose of connecting the Madras Observatory with the midnight and noon guns, the Indian Government has voted 200*l.*

MUSICAL INTERVALS

A BRIEF summary of the remarkable papers on musical intervals, by MM. Cornu and Mercadier, published in the *Comptes Rendus* of February in last year, may perhaps interest those of the readers of NATURE who have not met with the original.

The authors remark, in the first place, that two schemes of musical intervals have been proposed, in which the ratios of the number of vibrations in a given time are as follows :—

	Octave.	Fifth.	Fourth.	Major Third.	Minor Third.	Sixth.	Seventh.
(1)	2	$\frac{3}{2}$	$\frac{4}{3}$	$\frac{3^4}{2^6}$	$\frac{2^5}{3^3}$	$\frac{3^3}{2^4}$	$\frac{3^5}{2^7}$
(2)	2	$\frac{3}{2}$	$\frac{4}{3}$	$\frac{5}{4}$	$\frac{6}{5}$	$\frac{5}{3}$	$\frac{15}{8}$

and the object of the paper is to examine the claims of each for adoption.

On comparing these two systems, it may be observed that the Octave, Fifth, and Fourth are the same in both, and that the other intervals are connected by the following relations :—

$$\frac{3^4}{2^6} = \frac{5}{4} \times \frac{81}{80} \quad \frac{2^5}{3^3} = \frac{6}{5} : \frac{81}{80} \quad \frac{3^3}{2^4} = \frac{5}{3} \times \frac{81}{80} \quad \frac{3^5}{2^7} = \frac{15}{8} \times \frac{81}{80}$$

A third view of the subject, according to which either of the two systems may be adopted indifferently, because they differ only by a "comma" (an interval represented by 81 : 80), may be at once dismissed, since, as a matter of fact, the ear is capable of appreciating intervals much smaller than the comma.

As regards the scheme (2), it seems impossible not to admit that a major third is most harmonious when the resultant tone is exactly the double octave below the fundamental note, *i.e.* when the interval is represented by the ration 5 : 4. Any deviation from this proportion produces unpleasant beats. This argument seems decisive in favour of (2).

On the other hand, an ear which hears successively the notes emitted by an entire string, and by $\frac{4}{5}$ths of its length, will pronounce the third so formed to be too low. And, in fact, stringed instruments for concerted music are tuned by perfect fifths. Thus the intervals given by the violoncello, alto, and violins, &c., in a concerto would be c, g, d', a', e''.

But this involves a third (c, e) defined by the ratio $\frac{3^4}{2^6}$; for e must be the double octave below e'', and the interval (c, e'') is by hypothesis $\left(\frac{3}{2}\right)^4$; hence

$$(c, e) = \frac{1}{2^2}\left(\frac{3}{4}\right)^4 = \frac{3^4}{2^6}$$

which is the ratio for a major third according to scheme (1).

Thus, experiment apparently gives contradictory results.

The authors of the paper then proceed to describe a series of experiments made with the voice, violoncello, violin, organ-pipes, and monochord, all of which lead to conclusions reconciling this apparent contradiction, viz. :—

That musical intervals do not belong to any single scheme, but that the ear is capable of distinguishing between the intervals of the two schemes in question, and requires,

(*a*) When notes are heard in succession, forming what is called melody, that the intervals should belong to a series of fifths, in accordance with scheme (1) ;

(*b*) When notes are heard simultaneously, forming chords, or harmony, that the intervals should be adjusted according to scheme (1).

The details of the experiments, which are well worth study, would be too long to give in *extenso*; but the subjoined table will enable the reader to form a judgment of the results.

Notes produced by	Major Third.		Fifth.	
	Harmony.	Melody.	Harmony.	Melody.
Voice	—	1.260	—	1.497
Violoncello	1.251	1.266	1.499	1.508
Violin	1.249	1.264	1.504	1.504
Organ pipes	1.252	1.267	1.493	1.497
Monochord	—	1.271	—	1.500
Mean of observation	1.251	1.266	1.499	1.501
Calculation	$\frac{5}{4}$ = 1.250	$\frac{81}{64}$ = 1.2656	$\frac{3}{2}$ = 1.500	1.500

The direct experiments were made with these two intervals only ; but the same conclusions are shown to apply to the other intervals.

The authors then proceed to inquire whether there is any reason for limiting the prime numbers which enter into the ratios of the harmonic intervals to those (1, 2, 3, 5) actually occurring in scheme (1). An answer to this question is found in the chord of the dominant seventh, usually defined as the common chord with the addition of a minor third (*e. g.* Do, Mi, Sol, Si♭). The ratios of these intervals, according to scheme (2) are

$$1 : \frac{5}{4} : \frac{3}{2} : \frac{3}{2} \times \frac{6}{5} = 20 : 25 : 30 : 36$$

and the simplest whole numbers near to these are 4 : 5 : 6 : 7 ; and these, it is argued, are in fact an improvement on the former. For the ear, which alone can decide the question, will choose those notes which will form a chord devoid of beats, and whose difference tones do not introduce any notes foreign to the chord itself. Now

$$7-6 = 1,\ 6-5 = 1,\ 5-4 = 1$$
$$7-5 = 2\ \ 6-4 = 2$$
$$7-4 = 3$$

So that from the chord 4 : 5 : 6 : 7, we obtain the group of difference tones 1, 2, 3, all of which belong to the natural series terminating with the chord itself. While from the chord 20 : 25 : 30 : 36 = 4 : 5 : 6 : 7·142. we at once derive an inharmonious difference tone. This *a priori* conclusion may be verified on the violin, by first tuning the two upper strings in unison ; then by shortening one of them so as to form a minor third (6 : 5) with a difference tone 1 ; and finally, shortening the other until the difference tone 1 is again heard. This will, of course, give an interval (7 : 6) perfectly agreeable when sounded simultaneously, but not so when sounded in succession. In the same way the ear might be called upon to decide whether the numbers 11, 13, &c., are or are not admissible in harmony.

I trust that this very brief abstract may induce some of your readers to examine the paper itself.

W. SPOTTISWOODE

ON THE GREAT MOVEMENTS OF THE ATMOSPHERE *

MY original paper was based on the mean monthly pressures calculated for 516 places, and on the mean monthly direction of the wind calculated for 203 places over the whole surface of the earth. From these mean pressures the monthly isobars were drawn for every tenth of an inch, a pressure of thirty inches and upwards being represented on the charts by red-coloured isobars, and pressures of 29·9 inches and less by isobars coloured blue. Thus the distribution of the mass of the earth's atmosphere from month to month was graphically represented, the red lines showing

* This paper, presented to the recent meeting of the "British Association" at Liverpool, is a brief *résumé* of a paper, and the discussion which followed, "On the Mean Pressure of the Atmosphere, and the Prevailing Winds over the Globe for the Months and for the Year," originally read before the Royal Society of Edinburgh, and published in the Transactions of that Society in the beginning of December last.

where there was an excess, and the blue lines where there was a deficiency. The general results are that, in each hemisphere, pressures are highest in winter, and lowest in summer; that in winter the highest pressures are grouped over the continents, and in summer the lowest, and that in winter very low pressures prevail in the northern parts of the Atlantic and Pacific oceans respectively. The position of the isobars is wholly determined by the relative distribution of land and water.

As regards wind, those places were selected which are favourably situated for observing its direction. In calculating the average direction, the element of force was wholly excluded. The years were, so far as possible, the same as those for which the mean pressure had been calculated; but where this was not possible, care was taken to see that a good average was in every case obtained. The mean direction of the wind for each month is shown in the charts by arrows.

Thus two quite distinct facts were exhibited on the charts, viz. lines showing the mean pressure of the atmosphere, and arrows showing the prevailing winds at the earth's surface, each being independently arrived at by the summing and averaging of observed facts. What relation is there between these two classes of facts?

1. *As regards regions of Low Pressures:*

In every case where such occur at any season, it is universally seen that the relations of the winds to the isobaric lines is exactly the same that is illustrated in every storm of wind when the winds and pressures are set down in synophic charts.—The relation is this; the wind neither blows round the centre of least pressure in circles, nor as tangents to the concentric isobaric curves, nor does it blow directly towards that centre, but it takes an intermediate direction, approaching however more nearly to the direction and course of the circular curves than of the radii to the centre. The angle is not a right angle but from about 60° to 80°. Thus the whole system of winds seem to blow vorticosely in upon the spaces of low pressure. This is the relation known as *Buy's Ballot Law of the Winds.*

2. *As regards regions of High Pressures:*

In all cases where such occur, the winds are seen to flow out in every direction. In these cases also, the behaviour of the winds differs in no respect from what occurs on particular days on which the isobaric lines present the same conditions of pressure. The winds flow out of these spaces of high pressure in courses exactly the opposite to what takes place when they flow in upon spaces of low pressure, and hence such meteorological phenomena have been called by Mr. Francis Galton, "Anticyclones." This is also, it will be seen, in strict accordance with Buy's Ballot Law. Hence then this broad result is arrived at, viz., that the prevailing winds over the globe at all seasons obey Buy's Ballot Law, with reference to the distribution of atmospheric pressure.

The *outflow* of the air from a region of high pressure, and the *inflow* upon a region of high pressure is reducible to the single principle of gravitation, and so marked is this, that if there be any other force or forces which put the winds in motion, they must be altogether insignificant as compared with gravitation.

The annual averages of the 115 places distributed over the north temperate zone were minutely examined with the view of ascertaining how far the commonly-alleged prevalence of equatorial and polar currents is borne out by observation. The result of the analysis is this:—There are two maximum directions of prevailing winds at the stations of which the S.W. and N.E. at Greenwich may be taken as an example. The chief prevailing winds of the north temperate zone blow from some point from S.S.W. to W. (the true equatorial direction) at 41 per cent. of the stations, leaving 59 per cent. at which they are from other points of the compass. And the secondary prevailing winds come from some point from N.N.E. to E. (the true polar direction) at 34 per cent. of the stations or only a third of the whole. Hence whilst the largest percentage of prevailing winds are in the direction in which truly equatorial and polar winds should blow, the percentages from the direction are so large as to preclude the supposition of a general flow of the surface winds of the temperate zone towards and from the polar regions. The truth is, it is not the poles of the earth, but the regions of high and low pressures which must be regarded as the true poles of the winds towards which and from which the great movements of the atmosphere proceed; and owing to the unequal distribution of land and water, the poles of pressure and movements of the atmosphere are, as in the case of the poles of temperature, very far from being coincident with the North Pole.

The causes which bring about an unequal distribution of the mass of the earth's atmosphere are chiefly two—viz., the temperature principally, and secondarily the moisture of the atmosphere, their relations to the geographical distribution of land and water. The charts show that where there is an excess of temperature, as in the interior of Asia in summer, and where there is a relative excess of moisture, as in the belt of calms and in the north of the Atlantic in winter, and where there is an excess of cold, as in the interior of Asia in winter, and where there is a deficiency of moisture—there atmospheric pressure is high. Hence where pressures are low there the air is specifically light; and where pressures are high there the air is heavy relatively to that of surrounding regions.

Further, since vast columns of air are poured by the prevailing winds into those regions where pressures are low without increasing that pressure, we must suppose that there is an outflow from these regions through upper currents, and this inference is all the more inevitable, seeing that the specifically light air resting over these regions supplies the conditions of an ascending current. Again, since vast volumes of air are driven off from the regions of high pressure without diminishing the pressure, it must be inferred that the high pressure is maintained by accessions poured in upon it by the upper currents, and this inference is the more certain because in such regions the air is relatively heavier than in surrounding regions, thus supplying the conditions of a descending current.

It is evident that the currents from the regions of low pressure will continue to ascend as long as their pressure is less than that in regions surrounding them *at the same height*, but that as soon as they reach a height where the pressure is less, towards and over that region will they flow as upper currents of the atmosphere. The courses of these upper currents will be directed towards those regions where the air is coldest and driest near the surface of the earth, because being thereby densest, the great mass of the air will condense in the lower beds, thus leaving less air or a diminished pressure in the upper regions. Thus the high winter pressure of Asia will be maintained by air being poured upon it by upper currents from the regions of low pressure in the north of the Atlantic, the north of the Pacific, and the Equatorial regions of the south.

From these considerations the following *Theory of the Movements of the Earth's Atmosphere* necessarily follows. The winds on the surface of the earth are known from the isobaric lines, the direction being from regions of high towards regions of low pressures, subject to the changes produced in the direction of the currents by the earth's rotation; and the upper currents of the atmosphere may be inferred from the isobaric lines taken reversely together with the isothermal lines taken directly. In other words, the regions of lowest pressure, by giving the ascending currents, point out the sources or fountains whence the upper currents flow; and the isothermal lines, by showing where, on account of the low temperature, the greatest portion of the air is condensed in the lower beds and so diminishing the pressure in the upper beds, point out the regions towards and over which the upper currents diffuse themselves.

In this discussion of the prevailing winds and mean atmospheric pressure over the globe, there is contained the first approximate answer to the two questions:—

1. What are the motions of the earth's atmosphere?
2. What are the causes of these motions?

It has been shown by Dr. Balfour Stewart* that these questions form the first two stages in the development of meteorology. Considering the importance of the subjects of this discussion which enter deeply into Physical Geography, Geology, the Science of Navigation, and the General Physics of the globe, it is to be hoped that observation will be made and turned to account in rectifying the isobaric lines and filling up the blanks of the winds over the ocean, and portions of Africa and South America, data from these regions being in this as well as every similar discussion to a large extent wanting. ALEX. BUCHAN

SOCIETIES AND ACADEMIES

LONDON

Zoological Society, November 15.—Prof. W. H. Flower F.R.S., V.P., in the chair. An eighth letter was read from Mr. W. H. Hudson, containing further observations on the Ornithology of Buenos Ayres.—Mr. Sclater exhibited a specimen

* See NATURE of December 2, 1869, p. 129.

of the new Australian Mudfish, recently described by Mr. Krefft in the Society's "Proceedings" as *Ceratodus forsteri*. This specimen had been obtained from the Mary River, Queensland, and forwarded to Mr. Sclater by Mr. E. P. Ramsay.—Dr. J. Murie read a memoir on the form and structure of the Manatee (*Manatus americanus*), as deduced from a fresh specimen of this animal forwarded to this Society in a living state by Mr. G. W. Latimer, of Porto Rico, in April 1866, but which had unfortunately died just before reaching Southampton.—A communication was read from Mr. Morton Allport, relating to the progress of the experiments for introducing Salmon and Trout into Tasmania.—Professor Flower read a memoir on the anatomy of the Panda (*Ailurus fulgens*), as deduced from a specimen of this animal which had been presented to the Society by Dr. Simpson, in May 1869, and had lived for some time in the Society's Gardens. After an elaborate examination of every part of this animal, Professor Flower came to the conclusion that it belonged to the Arctoidean group of the Carnivores, and was most nearly allied to the Raccoons and other members of the family *Procyonidæ*. Mr. Bartlett read some notes chiefly on the habits of the same animal, as observed when living in the Society's Gardens.—A communication was read from Dr. J. E. Gray, containing the outlines of a new arrangement of the Delphinoid Whales.—A communication was read from Mr. W. Harper Pease, containing remarks on the Mollusks of the genus *Triphoris* and descriptions of some new species.—Mr. A. G. Butler communicated a notice of some abnormalities observed in the neuration of the hind wings in *Acræa andromacha*.—A paper was read by Dr. A. Günther containing descriptions of two new species of Lizards of the genera *Eumeces* and *Calotes*, proposed to be called *E. brachydactylus* (from Pegu) and *C. jerdoni* (from the Khasya hills).—A paper was read by Messrs. Sclater and Salvin on the recent collections of Venezuelan birds made by Mr. A. Goering in the vicinity of Merida. The present collection was stated to embrace examples of 105 species, nine of which were considered to be new to Science. Amongst the latter were two new Parrots, proposed to be called *Urochroma dilectissma* and *Conurus rhodocephalus*.—A communication was read from Mr. H. Adams, containing descriptions of 27 new species of Shells collected by Mr. R. McAndrew in the Red Sea. A second communication from Mr. Adams contained descriptions of a new genus and four new species of Shells from Borneo and other localities.

Anthropological Society of London, November 15.—Dr. Charnock, V.P., in the chair; H. R. Adam, and David Kinloch, were elected fellows. Dr. R. H. Bakewell read a paper on "The Condition of the Blood-corpuscles in certain Races." The author's researches had been undertaken at the request of Dr. Barnard Davis, F.R.S. While investigating the pathology of malarious fevers, the writer made numerous microscopical examinations of the blood, both of the sick and the healthy, in Trinidad. On comparison of the various races of English, French, Portuguese, Italians, Germans, Indians, Chinese, Africans (both indigenous and of West Indian birth), and Creoles of various breeds, he found that, besides the differences produced by disease, there were well-marked differences between the various races. The corpuscles of the flesh-eating Mussulman and the vegetable-feeding Hindoo were contrasted, and it was found that the Hindoo's blood contained a much larger number of white corpuscles, the red corpuscles also differing in form from those of the Mussulman. The author coined the word "nummulation" for the phenomenon observed in the aggregation of the corpuscles like *rouleaux* of coin. He gave the results of the examination of the blood of about a hundred different persons.—Mr. C. Staniland Wake, Director A.S.L., then read a paper on "Tribal Affinities among the Aborigines of Australia." After tracing the distribution of the several forms of native habitations, canoes, and weapons, and also of certain burial customs and initiatory rites, and referring to the apparently universal practice of cannibalism and blood-revenge, the writer stated, firstly, that the phenomena presented by the generality of the western natives are, on the whole, of a more simple character than those exhibited by the other aborigines agreeing with the milder disposition they apparently possess; secondly, that the southern and eastern natives agree generally in their customs with the aborigines of the western part of the continent, but that they present certain peculiarities which seem to suggest an internal influence. This influence must have proceeded from the north, and there the very customs of phenomena which constitute the differentia between the natives of the west and those of the east are met with. Comparing the distribution of initiatory rites with that of other customs, it would seem that scarifying the flesh and nose-perforation are, like the use of the semi-circular hut, primitive customs at one time common to all the aborigines; that the custom of removing a front tooth is almost limited to the canoe-making peoples of the north, south, or east, who also possess in common certain funeral rites unknown to the western natives; whilst circumcision is limited to the northern and southern tribes and to some intermediate ones. The final conclusion of the paper was, that the western natives represent the most primitive and simple form of the Australian stock, the natives of the south and east having been intermixed with fresh comers from the north, who introduced new customs. This southward movement was in two directions—one across the continent to the head of the Great Bight, thence spreading east and west along the coast; the other along the north and eastern shores, and gradually spreading over the eastern portion of the continent.—Dr. Robert Peel contributed a communication on Australian Aborigines and Half-Castes, and exhibited skulls (which he had presented to the Society's Museum) in illustration.

Chemical Society, November 17.—Prof. Williamson, F.R.S., President, in the chair. The following papers were read:—"Mineralogical Notices," by Prof. Maskelyne and Dr. Flight. The contents of this communication were—1. On the formation of basic cupric sulphate. In 1867 M. Pisani described a mineral which he supposed to be the Woodwardite of Mr. Church. The substance, however, is not the latter mineral. It had previously been examined in the Laboratory of the British Museum, and the results sufficiently tallied with those of M. Pisani to identify the mineral. The only interest this mineral offers is in the light it seems to throw on the possible modes of the formation of native basic cupric sulphates. The actions of solutions of magnesium or calcium sulphate on malachite may terminate in the production of langite. An experiment in the laboratory showed that an insoluble cupric sulphate and acid magnesium carbonate were actually formed. 2. Opal from Waddela Plain, Abyssinia. Mr. Markham presented to the British Museum some remarkable specimens of green opal from the above locality. Its analysis showed it to consist of about 92 per cent. of silica, 6 per cent. of water, and the remainder was iron, manganese, calcium, and magnesium. 3. Francolite, Cornwall. Its analytical numbers point to the formula

$$\left.\begin{matrix}5\,[3\,\mathrm{Ca},\ 2\,(\mathrm{P\,O_4})]\\ \mathrm{Ca\,CO_3}\end{matrix}\right\} + 2\,\mathrm{Ca\,F_2}$$

It is, in fact, a fluor-apatite, in which one equivalent in every six of the calcium phosphate is replaced by carbonate. The crystallography of this mineral seems also to point to its not being ordinary apatite, and in fact to its not being the same mineral as the original francolite from Wheal Franco. 4. Epidote and serpentine, Iona. A pebble in which a green mineral traverses bright red felspar and quartz in veins was sent by the Duke of Argyll to the British Museum. Its analysis leads to the view that it consists of a lime epidote with some 23 per cent. of quartz, the former mineral having the following constitution:

$$3\,[2\,\mathrm{Ca\,O},\ \mathrm{Si\,O_2}] + 2\,[2\,(\tfrac{3}{5}\mathrm{Al}\ \ \tfrac{2}{5}\mathrm{Fe})_2\mathrm{O_3},\ 3\,\mathrm{Si\,O_2}]$$

Two specimens of serpentine from the same locality gave the general formula:

$$3\,\mathrm{R''\,O},\ 2\,\mathrm{Si\,O_2},\ 2\,\mathrm{H_2\,O},$$

where R represents in one case Mg, with a little Fe and Ca; in the other Mg, with nearly one-fifth of its equivalent of an equal mixture of Fe and Mg. 5. Vivianite. Two kinds of this mineral were found in an unknown Cornish locality. The one is of a pale, bluish tint, the other of a brownish colour. Both proved to be octahydrated ferrous orthophosphate, $3\,\mathrm{Fe\,O},\ \mathrm{P_2\,O_5},\ 8\,\mathrm{H_2\,O}$, and the difference in the colours can only be ascribed to some minute difference in the degree of oxidation of the iron. 6. Cronstedtite. The analysis of this mineral presented considerable difficulties, inasmuch as it was extremely difficult to free it from the substances with which it is found associated. The cronstedtite in question possesses an unusual interest from a crystallographical point of view, being one of the best defined types of hemimorphism. 7. Pholerite. This mineral, derived from India, is of a pale flesh white, penetrated in several places by patches and veins of a black mineral. A new name was proposed for this mineral, but the analysis shows it to be nothing but pholerite. Mr. Church observed that it was a matter of congratulation to have those beautiful specimens which are stored in our magnificent national collections investigated in so excellent a manner as the contents of the paper just read have shown.—The next communication was a note by Mr. Chapman "On the Oxides of Nitrogen." In a paper read at the last meeting of the Chemical Society, Mr. Chapman mentioned that he had quantitatively estimated nitric oxide by converting it into nitric acid, and determining the latter by the production and weighing of the baryta salt. Objections were then raised as to the possibility of the completeness of such a conversion. Mr. Chapman now endeavoured to show by referring to well-known chemical facts that whether $N_2 O_5$, $N_2 O_4$, or $N_2 O_3$ be formed when $N O$ is left with excess of oxygen over water, the final result must be the transformation into nitric acid. Mr. Harcourt reasserted that on his passing nitric oxide into oxygen he obtained as result nitric peroxide; when reversing this order and passing oxygen into nitric oxide, a mixture of $N_2 O_4$ and $N_2 O_3$ seems to be formed. Mr. Chapman replied that the different results obtained by Mr. Harcourt and by himself were in all probability due to differences of the temperatures at which the respective experiments had been executed. Prof. Williamson took occasion of this repeated mentioning of nitric peroxide to remark that this compound may be viewed as $\left.\begin{matrix} N O \\ N O_2 \end{matrix}\right\} O$, *i.e.*, as water in which the one hydrogen was replaced by $N O$, the other by $N O_2$.

Linnean Society, November 17.—Dr. J. D. Hooker, V.P., in the chair. Notes on the *Passifloreæ*, by Dr. M. T. Masters. The paper treated of the morphology of the whole order, including the organography of all the genera; the minute anatomy, development, mode of fertilisation, and the movements which take place in the stamens and pistils of *Passiflora*; the affinities of the order, together with an inquiry into the value of characters, and the mode of estimating them; a complete list of the genera and species, with detailed descriptions of all the species which are not either American or African, and which will be published elsewhere; and, lastly, an account of the geographical distribution. (1.) Organography.—The tendrils, as shown by their development, minute anatomy and position, and the fact that they occasionally bear flowers, are merely modified flower-stalks. The leaf, whether single or divided, always commences in development at the apex, and proceeds from above downwards. There are only three bracts instead of five, as there would be in a perfectly symmetrical arrangement; their position, as well as that of the other parts of the flower, relative to the axis has been somewhat incorrectly described by Payer, Griffith, and Schleiden. Jussieu and St. Hilaire held that there is no true corolla in the passion-flowers, but two calycine whorls, because both organs fall at the same time. But the mode of development and the internal structure clearly demonstrate that the inner whorl is a true corolla; the calyx is quincuncial, while the petals appear simultaneously. The flower-tube is, according to Bentham, composed of a union of the calyx and corolla; Dr. Masters, on the other hand, believes it to be an expansion of the axis. Its development is comparatively late. The form of the corona was traced from its simplest form in *Turnera* to its most complicated arrangement in some Modeccas and Passifloras, in all cases it is a mere projection from the flower-tube, and is of late development, and morphologically of little importance, though essential to the individual life of the plant. The inner portion of the tube is a glandular secreting surface. Each separate thread of the corona has its own distinct vascular bundle. The stamens, unlike those of *Cucurbitaceæ*, are not perigynous, but truly hypogynous. The gynophore becomes gradually developed, raising the stamens with it. The anthers are invariably two-celled. The pistil is singularly uniform, one-celled, made up of three united carpels, with three parietal placentæ and three stigmas. (2.) Mode of Fertilisation.—The arrangement of the sexual organs favours cross-fertilisation. The anthers, originally introrse, become, when fully developed, distinctly extrorse, and it is thus rendered difficult for the pollen to fall on the stigmas of the same flower; it falls on to the rays of the corona, on which insects alight in search of the honey concealed at the base of the tube, and carry the pollen away to other flowers. Some species are more easily fertilised by pollen belonging to a different species than by their own; hence hybridisation abounds. (3.) Affinities.—Dr. Masters connects the *Passifloreæ* rather with the *Turneraceæ*, *Samydaceæ*, *Violaceæ*, and *Sauvagesieæ* than with the *Cucurbitaceæ*, chiefly on account of their truly hypogynous stamens. (4.) Geographical Distribution.—The order is essentially tropical, occurring between 30° N. and 30° S. latitude. Taking the genus *Passiflora* as the type, it is almost exclusively American, and chiefly Brazilian; a few outliers of the true passion-flowers occur in Madagascar and Mauritius, the latter probably introduced, and in North America there is a very remarkable form, the *P. incarnata*, or original passion-flower of the Jesuits; it is an annual, and apparently an alien, but remarkably uniform and invariable; its representative in Brazil is *P. edulis*, a shrub, and an extremely variable plant. On the western side of the Andes you get entirely different forms, especially the *Tacsonias*, which have generally a much longer flower-tube. In India there are a few species, not belonging to the American section of the order, but to the *Polyanthea*, which are found also in Ceylon and the Indian Archipelago, and one outlying species in an island aear Hong Kong. In Australia and the Pacific Islands occurs another perfectly distinct group; in New Zealand a perfectly distinct form is met with; and, again, another in Africa, where no true passion-flower is indigenous, except the one in Madagascar; the species here, few in number, belonging to six or eight distinct genera.—"On the White-beaked Bottle-nosed Whale," by Dr. Jas. Murie. The paper gave an account of several anatomical points in the structure of this whale, which had not been clearly described before. The little bag or sac connected with the double articulation between the lower jaw and the rest of the skull, which is found in all Mammals except the Cetacea, is however, present in the fœtus of the latter.

Mathematical Society, Nov. 10.—Prof. Cayley, President, in the chair. The following gentlemen were elected to form the council for the Session 1870–1:—President, W. Spottiswoode, F.R.S.; Vice-Presidents, Professors Cayley, Henrici, and H. J. S. Smith; Treasurer, Dr. Hirst; Hon. Secs., M. Jenkins and R. Tucker; other Members, W. K. Clifford, T. Cotterill, M. W. Crofton, *C. W. Merrifield, *J. F. Moulton, J. Stirling, Archibald Smith, Prof. Sylvester, J. J. Walker. Mr. J. J. Hamblin Smith, M.A., Caius College, Cambridge, was proposed for election. The new president having taken the chair, called on Prof. Cayley to read his paper, of which an abstract is given below—"Sketch of Recent Researches upon Quartic and Quintic Surfaces." The classification of quartic surfaces is, even as to its highest divisions, incomplete; and it is by no means easy to make it at once exhaustive and precise; an examination of all the *prima facie* possible cases would include forms which do not really exist. Premising that the expression "singular" means double or cuspidal, or refers to a higher singularity; "nodal" in general double (including the signification cuspidal), we may provisionally arrange the non-scrolar quartic surfaces as follows—1, without a nodal curve; 2, with a nodal line; 3, with a nodal conic, or line-pair; 4, with three nodal lines (not in the same plane) meeting in a point); 5, the quartic scrolls, omitting altogether the torse and cones. For the scrolls the division into twelve species appears to be complete (Memoirs by Cayley (3) (4), Cremona, and Schwarz). As regards non-scrolar surfaces, we have—1. Without a singular curve. The surface may be without a cnicnode (conical point), or it may have any number of cnicnodes up to 16 (Cayley, (5); Kummer (1) (2),). It may be remarked that the wave-surface, or generally the surface obtained by the homographic deformation of the wave-surface, called by Cayley (1) (2) the "tetrahedroid," is a special form of surface with 16 nodes. 2. Quartic surface with nodal line. Considered incidentally in *Clebsch* (2) (3). 3. Quartic surfaces with nodal conic. Such a surface may be without cnicnodes, or it may have one, two, three, or four cnicnodes. The cases other than that of three cnicnodes are mentioned, *Kummer* (1); but the question is examined and the remaining case of three cnicnodes established, *Cayley* (6). The general case of the nodal conic without cnicnodes is elaborately considered, *Clebsch* (1). See also *Geiser*; the several cases of one, two, three, and four cnicnodes are considered, *Korndorfer*. In the case where the nodal conic is the circle at infinity the surfaces have been termed "anallagmatic" (perhaps "bicircular" would be a more convenient name), and a great deal has been written on these surfaces by Moutard, Clifford, and others. The theory of the quartic surfaces with a cuspidal conic has been hardly at all considered, briefly referred to in *Cayley* (6), also in *Cayley* (8). "I do not know that anything has been done in regard to the quartic surfaces where the nodal conic becomes a line-pair, that is, where we have two intersecting nodal lines." 4. Quartic surface with three nodal lines (not in the same plane) meeting in a point. This is in fact *Steiner's* quartic surface, and it has been the subject of numerous investigations. The author then

* These gentlemen were not on the Council for the Session 1869–70.

proceeded to speak of the paper, *Kummer* (1), which discusses the cases in which a quartic surface has upon it a system of conics; or what is the same thing, in what cases there is a system of planes each intersecting the surface in two conics. It is, in the first place, remarked that there is no proper quartic surface cut by every plane in a pair of conics or even a proper quartic surface cut in a pair of conics by every plane through a fixed point. The cases considered are:—(I.) where the planes are non-tangent planes; (II.) where they are single tangent planes; and (III.) where they are double tangent planes (*Steiner's* surface, where every tangent plane meets the surface in a pair of conics, comes under II.). It was then pointed out that several of the papers by *Clebsch* and others, refer in their titles to the "Abbildung" of a surface, viz. they show that a (1, 1) correspondence exists between the points of a surface and the points of a plane. For surfaces of the higher orders it is only certain surfaces which admit of an "Abbildung," or (1, 1) correspondence of the points thereof with the points of a plane; viz. a surface, in order that it may thus correspond with the plane, (or say in order that it may be unicursal), must have a sufficient singularity in the way of a nodal or cuspidal curve. In the memoir *Clebsch* (3), after explaining the above method of the transformation of a cubic surface by means of two of the lines thereof, the author goes on to notice that the like method is applicable to certain quartic and quintic surfaces, viz. (1) quartic surfaces with a nodal conic; (2) quartic surfaces with a nodal line; (3) quintic surfaces having a nodal skew cubic (the nodal skew cubic may break up into a conic and line which meets it, or into three lines, two of them not meeting each other, but each met by the third line; and the like theory applies to these quintic surfaces). The memoir by *Korndorfer* relates to the "abbildung" of a quartic surface having a nodal conic, and one, two, three, or four cnicnodes. *Clebsch* (4) relates to the "abbildung" of a quartic scroll. "As regards quintic surfaces (not being scrolls), we have, so far as I am aware, only the paper *Clebsch* (3) relating to quintic surfaces with a nodel Skew Cubic; the paper *Clebsch* (5), which relates to the 'abbildung' of a quintic surface having a nodal quadriquadric. It only remains to speak of *Schwarz's* memoirs on Quintic Scrolls: it is to be remarked that the theory of scrolls is allied more closely with that of plane curves than with that of surfaces, viz. considering any plane section of the scroll the lines of the scroll have in general a (1, 1) correspondence with the points of the plane section, and the scrolls of any given order are properly arranged according to the deficiency of the plane section. This is what is done in the memoirs by *Cremona*, and this is the principle of classification in *Schwarz's* memoir. A model of Steimer's surface was exhibited, and many of its properties pointed out. The following list of memoirs will indicate the sources whence the sketch was principally drawn. Memoirs by the author: (1) Sur la Surface des Ondes. Liouville, tom. xi. 1846. (2) Sur un cas particulier de la Surface du quatrième ordre avec seize points singuliers. Crelle, tom. lxv. pp. 284—290. (3.) Second memoir on Skew Surfaces otherwise Scrolls. Phil. Trans. vol. cliv. (1864), pp. 559—577. (4.) Third memoir. Phil. Trans. vol. clix. (1869), pp. 111—126. (5.) A memoir on Quartic Surfaces. Proc. of London Math. Society (1870), vol. iii. pp. 19—69. (6.) On the Quartic Surfaces $(* \between, U, V, W)^2=0$, Quarterly Journal of Math. tom. x. (1868), pp. 24—34. (7) Do. tom. xi. pp. 15—25 (1870). (8.) Memoir on Cubic Surfaces. Phil. Trans. vol. clix. (1869), pp. 231—326. *Cremona:* Sulle superficie gobbe di quarto grado. Mem di Bologna, tom. viii. (1868). *Schwarz:* Ueber die geradlinigen Flächen fünften Grades. Crelle, tom. lxvii. (1867), pp. 23—57. *Clebsch* (1) Ueber die Flächen vierter Ordnung welche eine Doppelcurve zweiten Grades besitzen. Crelle, tom. lxix. (2.) Intorno alla rappresentazione di superficie algebriche sopra un piano. Atti di R. Ist. Lomb. (1868), 13 pages. (3.) Ueber die Abbildung algebräischer Flächen insbesondere der vierten und fünften Ordnung. Ann. Clebsch und Neumann, vol. i. (1868), pp. 253—316. (4.) Ueber die ebene Abbildung der geradlinigen Flächen vierter Ordnung welche eine Doppelcurve dritten Grades besitzen. Ann. Clebsch und Neumann (1870), pp. 445—466. (5.) Ueber die Abbildung einer Classe von Flächen, 5 Ordnung. Gött. abh. tom. xv. 64 pages. *Geisser:* Ueber die Flächen vierten Grades welche eine Doppelcurve weiten Grades haben. Crelle, tom. lxx. (1868), pp. 249—257. *Korndorfer:* Ueber die ebene Abbildung Clebsch und Neumann, tom. ii. *Kummer:* (1) Ueber die Flächen vierten Grades auf welchen Schaaren von Kegelschnitten liegen. Berl. Monatsber. Jul. 1863. Crelle, tom. lxiv. (1864), pp. 66—76. (2) Ueber die algebräischen Strahlensysteme ins besondere über die der ersten und zweiten Ordnung. Berl. abh. (1866), pp. 1—120. (3.) (Surfaces of the 4th order with sixteen conical points). Berl. Monatsber. (1864), pp. 246—260, and 495—499.

Meteorological Society, November 16.—Mr. C. V. Walker, President, in the chair. Mr. J. H. Gilbert, Mr. C. R. Marten, Mr. F. E. Sawyer, and Mr. T. H. Wilson were elected Fellows. A paper was read by Mr. G. Dines, "On Evaporation and Evaporation Gauges, with some remarks upon the Formation of Dew," in which, after referring to Dr. Dalton's investigations, he explained the experiments in which he has been engaged during the past eighteen months with gauges of different sizes, the experiments being made sometimes with water of ordinary temperature, and at other times with heated water and also with water artificially cooled, in the open air and in a closed room. Mr. Dines then gave the results of these experiments, one of which confirmed the statement of Mr. Glaisher in 1847, viz. that "the formation of dew was found to depend solely on the temperature of the bodies upon which it was deposited, and that it never appeared upon them till their temperature had descended below that of the dew-point in their locality." Finally, he stated that the conclusions which he had arrived at were, 1st. The greatest cause of evaporation is the movement of the air. 2nd. Whatever tends to increase the temperature of the air increases evaporation, and *vice versâ*; and 3rd, That which tends to lessen the temperature of the dew-point, increases evaporation, and *vice versâ*. Mr. Glaisher then made a communication respecting the November meteors, giving the results of the watches which were kept during the nights of the 12th-13th, 13th-14th, and 14th-15th. On the latter evening fifty-three meteors were observed. He also made some remarks on the great magnetic disturbances which occurred during the brilliant display of Aurora Borealis on the nights of October 24th and 25th. The President then adjourned the meeting till January 18, 1871.

MANCHESTER

Literary and Philosophical Society, October 4.—Rev. Wm. Gaskell, Vice-president, in the chair. Mr. Boyd Dawkins gave a short account of the work done in the Victoria Cave, near Settle, since the last notice brought before the Society. The two layers containing traces of man were separated at the entrance by a talus of fallen stones, seven feet thick, that gradually coalesced as the excavation passed into the cave, and at last became so confused together as not to be easily distinguished at a few feet from the entrance. The remains of a gigantic bear which had been eaten may probably be assigned to the lower horizon, which furnished flint-flakes, and a bone harpoon in form resembling that used by the natives of Nootka Sound; the upper or Romano-Celtic stratum continued to supply evidence of the comparatively late date of its accumulation in barbarous imitations of coins of Tetricus (A.D. 267-273.) A portion of the ivory handle of a Roman sword and a coin of Trajan have also been found, along with large quantities of the bones of animals that had been used as food. Several spurs of cocks proved that the inhabitants ate the domestic fowl, which was probably imported into this country either directly or indirectly by the Romans. The most striking object, however, is a beautiful sigmoid fibula made of bronze, and ornamented with a beautiful pattern in red, yellow, green, and blue enamel. It is an admirable example of the art of enamelling ("Britannicum opus"?) which the Celtic inhabitants of Britain probably taught their Roman conquerors.

October 18.—Mr. E. W. Binney, President, in the chair. Prof. Balfour Stewart, F.R.S., exhibited a series of sun-spot curves projected from results obtained by himself and Mr. De La Rue, from observations of Schwabe, Carrington, and the Kew series of photographs of the sun. These extend over a term o about forty years, and exhibit a principal and secondary maximum and minimum in each solar spot period of eleven years, thus corresponding with the light curves of R Sagittæ observed by Mr. Baxendell, and β Lyræ by Prof. Argelander. Hence it may possibly be that notwithstanding the darkening of the sun's surface during the maximum spot period, the total light and heat emitted by the sun at this period is really greater than at the times of minimum spot frequency.—Mr. Lockyer, F.R.S., gave an account of his recent spectroscopic investigations of the solar atmosphere, and pointed out that the conclusions arrived at by De La Rue, Stewart, and Loewy, confirmed the views to which he himself had been led by spectroscopic observations of the sun during the last two or three years. These tended to show that the absorbing atmosphere, termed the chromosphere, which he had proved to exist round the sun's body, had gradually diminished in thickness since the last solar spot minimum in 1867.—Mr. Boyd Dawkins, F.R.S., gave a short account of the examination of Offa's Dyke made in the autumn by Col. Lane Fox and himself. The portion examined extended from Cherbury in the south to the abrupt range of limestone hills to the north of Llanamynech. At Nantcribba Hall, near Forden, the dyke passes nearly due north between the road to Montgomery and the abrupt boss of volcanic trap which looks at a short distance like a ruined castle, and which has been encircled by a very broad and deep moat. There can be no doubt but that this was a point of observation, and as it is but some twenty yards on the English side of the dyke, it was most probably one of the permanent positions occupied by the English followers of the Mercian King. From this point the dyke gradually swerves to the east from the road between Montgomery and Buttington, and makes directly over the low slopes of the hills, in some places being nearly ploughed down, and in others, and especially in the small valleys, being of considerable height and resembling a railway embankment, until it reaches the higher ground of Fron. Thence it runs through Pentre and gradually approaches the road, and finally dies away in the alluvium of the Severn, nearly a quarter of a mile to the south of Buttington Church. The commanding camp to the south of this portion of the line is Caer Digol, or the Beacon Ring, on the top of the Long Mounain. The morass, which in Offa's time must have extended beween the main ditch and the Severn, prevented the necessity of any bank being made between Buttington and the Cefn. Where, however, the open country demands a defence to the north of Cefn, an embankment makes straight for the Greenstone ridge of the Garreg, and is very plainly seen close to the farm-house of that name, near the Trewern Gate. Here we lost our clue, and it is very likely that the steep ridges of Moel y Golfa, and the marvellously strong camps of the Breiddan and Middleton Hills, formed a sufficiently strong barrier without any dyke being raised. We picked it up again, however, on the western or Welsh side of the Severn, from which it runs, as shown in the Ordnance map, due north to the four crosses, where it joins the Oswestry road, and where it is cut across by the new railway. There it makes straight for the fortified hill of Llanamynech, its line coinciding with the high road. On reaching the summit of Llanamynech it takes the western or Welsh side of the two large camps, and passes down into the valley to the south of Whitehaven, which was the limit of our expedition. The results of our examination are the direct proof that the dyke was made for military purposes, and that it took the line which was best adapted for repelling the incursions of the Welsh. Throughout the district which was examined the embankment faces Wales, and was therefore made to defend the country within it from the Welsh. Dr. Wright's view, therefore, that it was a mere geographical boundary to prevent the Welsh from stealing the cattle of the Mercians cannot be maintained, although it may perhaps receive some confirmation from the nursery legend of Taffy. The camps in the neighbourhood of the dyke are probably older than Offa's time. The bronze spears found in Llanamynech imply that the camp is not later than the bronze age, while the Roman coins in that of the Breiddan point to its occupation by the Romans.

November 1.—Rev. William Gaskell, Vice-president, in the chair. Mr. William H. Johnson, Mr. Walter Morris, and Professor Balfour Stewart were elected ordinary members of the Society. Dr. Joule exhibited a series of curves obtained by Dr. Stewart from the self-recording instruments at the Kew Observatory, showing a large amount of disturbance of the magnetic declination and horizontal force during the progress of the aurora of the 25th October. He also showed a curve of the changes which took place in the magnetic dip as observed by himself at Broughton. The most remarkable variation occurred during the interval from $6^h\ 15^m$ to $6^h\ 23^m$ G.M.T., when the dip increased from 69° 8′ to 70° 30′.—"Notes on Glacier Moraines in Cumberland and Westmoreland," by Mr. Brockbank, F.G.S. The author referred to the proceedings of the Geological Society of London for 1840—1, which contain notices of the evidences of glaciers having existed in Great Britain, by Professor Agassiz, Dr. Buckland, and others, and which point out (1) "Moraine-like Masses of Drift," which occur near the junction of the Eamont and Lowther with the Eden, near Penrith; (2) The "large and lofty insulated piles of gravel in the valley of the Kent near Kendal, and the smaller moraines and their detritus, which nearly fill the valley from thence to Morecambe Bay;" (3) "Similar mounds near Shap," and (4) the "Gravel mounds near Milnthorpe and thence to Lancaster." Of these the author considered the Kentmere Group, near Kendal, as most nearly fulfilling the conditions required in true glacier moraines, and that in the other cases it admitted of doubt whether they were really due entirely to glacial action. The districts more particularly the subjects of the author's notes are (1) the valleys of Eskdale and the Duddon (which were not visited by Dr. Buckland, but in which he supposed moraines to exist, from the appearances of the valleys as delineated in Fryer's map of Cumberand); (2) the valleys eastwards from Bowfell; and (3) the district of Shap Fells.

DIARY

THURSDAY, NOVEMBER 24.

LONDON INSTITUTION, at 7.30.—On the Precious Metals and their Distribution: Prof. Morris

ROYAL SOCIETY, at 8.30.—Note on the Pendulum Observations in India: Col. J. T. Walker, F.R.S.—The Theory of Resonance: Hon. J. W. Strutt.

SOCIETY OF ANTIQUARIES, at 8.30.—Romano-Celtic Sword exhibited by Lord Wharncliffe: Mr. A. W. Franks.—Wall Decorations of the Roman Period in Sectile Work, especially in Glass: Mr. A Nesbitt.

SUNDAY, NOVEMBER 27.

SUNDAY LECTURE SOCIETY, at 3.30.—On he Antiquity of Man: Dr. Cobbold.

MONDAY, NOVEMBER 28.

LONDON INSTITUTION, at 4.—On Chemical Action: Prof. Odling

INSTITUTE OF ACTUARIES, at 7.—On Legislation in reference to Life Insurance and Life Insurance Companies: Mr. T. B. Sprague, M.A.

TUESDAY, NOVEMBER 29.

GEOGRAPHICAL SOCIETY, at 8.30.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY, at 7.

WEDNESDAY, NOVEMBER 30.

SOCIETY OF ARTS, at 8.—On Peat and its Profitable Utilisation: Robert M. Alloway.

THURSDAY, DECEMBER 1.

CHEMICAL SOCIETY, at 8.—On some Derivatives of Anthracene: Mr. W. H. Perkin.

LINNEAN SOCIETY, at 8.

LONDON INSTITUTION, at 7.30.—On Gems and Precious Stones: Prof. Morris.

SOCIETY OF ANTIQUARIES, at 8.30.

TUESDAY, DECEMBER 6.

ANTHROPOLOGICAL SOCIETY, at 8.—On the Races inhabiting the British Isles: Mr. A. L. Lewis.—On Archaic Structures of Cornwall and Devon: Mr. A. L. Lewis.—On Forms of Ancient Interment in Antrim: Dr. Sinclair Holden.

MEDICAL SCHOOLS IN ENGLAND AND GERMANY

III.

THERE is something elevating in the thought that the hospital, while it provides care for the sick, at the same time makes them useful for the purposes of instruction in the service of mankind. Still it is painful, on the other hand, to think that the patient enjoys this attention only in order to be made as profitable as possible to others; that he is given over to a crowd of curious seekers for knowledge, who feel his painful spots, percuss and auscultate his weakened body, and, in short, by proceedings of various kinds, disturb the rest he so heartily longs for. Such evils are not indeed of any account, so long as the number of students does not exceed a certain limit. Experience teaches that a patient is pleased to see a certain number of doctors about him; he soon gives them his confidence, he looks upon them as his friends, and willingly allows himself to be examined, partly with the idea that it will be better for him if the examination is several times repeated, partly in acknowledgment of kind attentions which are shown him. The difficulty arises when the number of students is so large that the patient can no longer feel at home with them. Apart from the fact that the disturbance of the patient increases with the increase of the crowd about him, it is also of the utmost importance to consider that the greater number of students must remain total strangers to him, that they are for him only intruders, who are learning from his body without offering him anything in return.

The situation becomes, however, actually distressing in the neighbourhood of a distinguished teacher in one of the large schools. An inquisitive throng crowds about the sick bed, utterly regardless of the patient's comfort. The hospital becomes a market, the sick merchandise.

Inasmuch as it is important for us to give the relations of hospital and school a basis as humane as possible, we must inquire what those large schools have to offer in the way of medical instruction, and whether we may take the advantages as a set-off to the evils.

As far as the art of medicine is concerned, we can maintain, without fear of opposition, that, *cæteris paribus*, clinical medicine will be taught with less success, the greater the number of students who crowd about the bed. The technical part of medicine should be taught orally. The student should be drilled in it as in a trade. In general, however, and to a certain point, the capability of the person so drilled increases in proportion to the time which the teacher devotes to him personally, and it must therefore be in inverse proportion to the number of pupils whom a teacher has to instruct.

Experience, in fact, teaches us that with large numbers of pupils the standard of individual capability is apt to be extremely low. In Vienna, where about 300 students are instructed in clinical medicine around each bed, the amount of drill which each receives comes so near zero that for practical life it is scarcely to be taken into account. The students discover this as soon as they have left their studies behind them and begin to look forward to practice. They distribute themselves then among the hospitals where there are no students' tasks, and there, with great loss of time, and under discouragements of many sorts, they are instructed in subjects which, according to their diplomas, they should have learned long before. Between such extreme unsuitableness and a really healthy state of instruction, there is, however, a long road leading us through many schools of various grades.

Instruction in medical science is good only where it happens to be endurable by the patient — that is, in smaller schools, where a few students only collect about his bed. Medical instruction has still another side. The student must not only learn the handicraft, he must also, through well-instructed teachers, be made familiar with the delicate processes which require delicate instruments, and experiments, and methodical thought for their elucidation; for it is only by intercourse with thinking men that he can learn how careful observation and earnest thought on the phenomena with which his whole life will be occupied, can be made available for practical ends.

In this connection, also, the question of the value of instruction in hospital wards must be answered. In point of fact the *practising physician* has always hitherto been regarded as the high school of medical science. Famous systems of medicine—that is, theories upon the nature of disease—took their start in hospital wards, and were taught at the bedside by distinguished masters.

In this country, however, a total revolution has taken place, speculations upon systems of medicine are supplanted by exact medical science, and this, for the moment, has fled from the ward and taken up its abode in the laboratory—here, at the present time, the most distinguished medical men and working pupils of superior gifts attach themselves to the laboratory, and remain there to study. Hence the phenomenon that, in Germany, in the department of pure clinical medicine, there is a want of worthy representatives. We are not to conclude on this account that our generation is inferior; it is only that the distribution of its scholars is different.

The modern students of clinical medicine seek to found their reputation by work in the laboratory, and they are unable to stand competition with those workers who are at home in it. First, because in general their ranks are not recruited by thinkers of the first order; secondly, because their profitable business coming in the way hinders their thorough education. They leave, therefore, the firm ground which the morphology of disease affords, and trust themselves to the weak ship of experimentation, which they are not able to steer.

Even if the results of such investigations are taught at the bedside, the highest school of medical science is not to be sought there. The patient ought not to be disturbed, and the drill of the student neglected, for the sake of a science which is, or ought to be, better studied in the laboratory. It is the morphology of disease which belongs directly to the sick bed. One must have seen distinguished teachers of this kind, one must have observed how they bring to light latent indications of disease, in order to concede that to such men, even a little misusage of the sick might be allowed in the interests of education. This bringing to light and grouping of phenomena for the purposes of diagnosis, is nowadays, indeed, not called science. It is an intellectual act, such as everyone performs when he defines a plant, a mineral, or a commodity. The combination of the symptoms and definition of the disease is, in fact, an important element of the physician's art, and must be included in every course of instruction. Still "Eines schickt sich nicht für Alle."

When Cuvier determined to what primeval animal a bone found buried in the earth must have belonged, it was only a definition; yet no one will hesitate to rank it amongst the noblest exercises of the human intellect. So, too, the diagnoses of distinguished masters may be ranked with the greatest achievements of medical investigators. To forbid such masters to teach at the bedside because many students crowd about them and disturb the patient, would be absurd. The instruction of such masters is, however, fit only for connoisseurs. For the uncultivated taste of the beginner it is unsuited. If it is besides so diluted as, with a large number of students, must invariably be the case, according to an unalterable law, it entirely loses its value. If, then, the founders of hospitals or their administrators would diminish to a certain definite and very low standard the number of students who, at one time, should be allowed to enjoy the privilege of instruction in a hospital ward, they would certainly do no injury to the interests of education. On the contrary, if liberal in other respects, they would, by such limitation, further these interests.

In what shall this liberality consist? Simply in this, that all available space in the hospital shall be open for the purposes of instruction, and that as many teachers shall be admitted as is consistent with a proper classification of the patients. We say *admitted*, and this is really the fittest expression, for there is not the smallest doubt that always and everywhere the ablest men would be eager to accept the place of teacher. The intellectual stimulus which an able physician derives from association with a school and intercourse with young men, and the moral support which a situation as instructor gives him in regard to his patients, are sufficient compensations for the required expenditure of time.

The physicians and surgeons who at present have large amounts of material at their disposal in large hospitals, would certainly not be willing to support such a system of division. They would complain that they are deprived of the possibility of attaining great skill. There is some truth in this objection. It is a benefit to mankind when a surgeon, by extensive practice, attains superior skill in the performance of certain operations. But the advantage which a few derive from his technical skill is counterbalanced by the loss which the rest sustain from the superficial manner in which they are passed over with a mere glance. In such a hospital more things are overlooked than one would imagine; and the pupils profit far less from the skill of the teacher than they lose from the superficiality of the teaching. It is, moreover, untrue that skill is likely to suffer from a further division of material. We have examples of great operators who never occupied a position in a hospital. Nor can it be doubted that the greater the number of those to whom the opportunity is given of proving their skill, the greater will be the number of skilful surgeons.

In the plan here proposed, many readers may see only what is already introduced in England, that is, small schools for the special study of medicine. The writer of this article is, however, far from speaking in behalf of schools of this kind. Such schools are fit only for the production of craftsmen; and medical men, though they must be craftsmen, must not be mere craftsmen. Such small special schools can serve only as preparatory appendages to the larger educational bodies, that is to say, to the Universities, whose function it is to foster the sciences for their own sakes.

Every medical student ought to obtain his education in general physical science and special medical science at the University; and while doing so he must acquire the art of medicine in a hospital, just as the young botanist must study in the field at the same time that he attends lectures.

The small Universities in Germany answer both purposes to an approximate degree. There one finds excellent schools with so few students that they can obtain both the higher scientific education and drill at once. To approach towards such circumstances, without giving up the great advantages which large schools offer for the development of science, is the end towards which we must strive.

S. STRICKER

POLARISATION OF THE CORONA

As this forms one of the most important questions to be settled during the coming Eclipse, it becomes desirable to reconsider the observations already made on this subject. Arago first suggested that the polariscope should be used on the corona, but apparently did not anticipate any decided results. The principal observations since made are the following:—

1842.—Arago at Perpignan. Used a polariscope *a lunulis*, that is, a double-image prism and crystal. He found the two images of complementary tints, the colour extending over the sky around the corona, the corona itself, and even over the disc of the moon.

1842.—Mauvais at Perpignan. Used a Savart's polariscope. He saw the bands very distinctly on the corona, and faintly on the moon itself. Their maximum of intensity corresponded with the horizontal position of the bands. Evidently he should have found another maximum when the bands were vertical.

Both this and the preceding observation show the existence of atmospheric polarisation extending even over the disc of the moon. Its plane must have been the same throughout, or Arago would have seen the different parts varying in tint. The maximum noticed by Mauvais shows that the plane must have been either vertical or horizontal, that is, not oblique.

1851.—Abbadie at Trocdesecksseverk. Inserted a plate of quartz between the object glass and eye-piece of his telescope, and applied a double refracting prism to the eye-piece as an analysis. He found the light of the corona strongly polarised, but saw no traces of colour on the moon. He was, however, troubled by clouds.

1851.—Dunkin at Christiania. Found no traces of polarisation, but was troubled by clouds.

1851.—Carrington at Lilla-Idel. Used a Nicol's prism, but found no polarisation.

1858.—Liais at Paranagua. Instrument used, a Savart's polariscope. He found the plane normal to the limb of the sun, and the intensity small, but greater than that of the moon.

He also remarks that the neutral point of sky polarisation was in the neighbourhood of the sun, a statement difficult to comprehend, as the neutral points are commonly defined by their distance from the sun.

1860.—Secchi on Mont St. Michel. Used an Arago's polariscope, and found that the images were not of equal colour, and that one was elongated in one direction, the other in a direction perpendicular to it. This last appearance was probably imaginary, as the crystal in the polariscope would prevent the extinction of any polarised rays.

1860.—Pragmowski at Briviesca. Used a plate of right and left-handed quartz at the common focus of the object glass and eye-piece, and a Nicol's prism in the eye-piece. This combination should give two semicircles of complementary tints when the plane of polarisation is oblique to the line of junction of the quartz. Using a power of 22, placing the line of junction vertical, and bisecting the sun, he found the top and bottom alone of uniform tint, the two semicircles being very strongly coloured, one red, the other green. He thence inferred a radial polarisation. In reality, in this case, he should have found the sides alike, as well as the top and bottom, only faint yellow instead of purple, and the colours most strongly marked at angles of 45°.

1868.—Campbell used a Savart's polariscope and found the bands strongly marked, having a maximum at 140° from the vertex.

1868.—Winter used a similar instrument, and, as a result, found the polarisation very strong, especially close to the sun.

1869.—Pickering at Mount Pleasant. The writer used an Arago's polariscope, and found the sky polarised close to the corona, the plane being the same on all sides of the sun.

1869.—Smith, at Eden Ridge, records a similar result obtained by a member of his party.

We see, therefore, that the results are very variable, the polarisation of the corona, if any, is obscured by that of the sky, probably due to secondary reflection. It is therefore very desirable to use some means of neutralising this effect. One remedy is to place a double-image prism in front of the telescope, which thus superposes two images of the sky polarised at right angles. For observations on the sky no telescope should be used, or the light will be too much enfeebled. A Savart's polariscope is the most delicate instrument, but such a one as the Arago is more useful to determine just what portion of the light is polarised. The Nicol's prism and the double-image prism give such indefinite results, that little could be expected of them, and they have been tried by several observers without success. The best instrument to measure the intensity of the polarisation is the polarimeter, consisting of several glass plates, which can be set at an angle in front of a Savart, and the point of disappearance of the bands recorded. The absence of polarisation of the protuberances has been observed by Abbadie, Pragmowski, and others, and seems so well determined, their further examination is unnecessary.

EDWARD C. PICKERING

THE RESOURCES OF LA PLATA

The Mineral and other Resources of the Argentine Republic. Published by special authority of the National Government by Major I. Rickard, F.G.S. (London: Longmans and Co., 1870.)

MAJOR RICKARD has executed in a very creditable manner the task which the National Government deputed him to perform, and his volume will give its readers considerable insight into the vast material resources of the Argentine Republic. Hitherto La Plata, in spite of its name, has been regarded rather as a field for agricultural enterprise than as a source of mineral wealth; and the stories which were once current of mountains rich in precious metals have been forgotten in the details given by our countrymen of their successful farming in the pampas of the south. Various causes have combined to divert attention from the mineral riches of the country. The tedious contest with Lopez, only just concluded, and the turbulent character of the gauchos and Indian tribes, have checked the growth of confidence in the minds of emigrants or capitalists; and though the vigorous administration of President Sarmiento has already done much to remove these obstacles, some time must still elapse before investors will be persuaded that "the great Republic of the South" is likely to realise all the favourable vaticinations of which Major Rickard makes it the subject. What, however, has most retarded the progress of mining, and, indeed, of all industrial enterprise, in the Argentine Republic, has been the deficient population and the want of means of intercommunication and transport. Buenos Ayres and the other riverine provinces, where grazing is a pleasant and profitable pursuit, absorb nearly all the working power of the Republic, and at the present time not more than 2,687 persons are engaged upon any form of mining industry. If the reader will cast his eye over a map of the country (the absence of which in Major Rickard's book is a serious defect), he will see what a mere scratching of the soil can be effected by such a handful of men. Hence it is that very trifling results have hitherto been obtained from the few mines yet in operation, and that the processes for reducing the ore have remained defective and costly. The supplies drawn from the Argentine Republic produce no appreciable effect upon the metal markets of the world, and in popular estimation its exports solely consist of tallow, wool, and hides.

President Sarmiento, a man of no common discernment, is convinced that the substantial wealth of his country is to be found in its mineral resources, and, moreover, that they will provide the surest means for promoting rapid and extensive immigration. In their development is bound up the extension of commerce and the progress of agriculture. Had it not been for the discovery of gold, California might still have remained a vast cattle range to this day; and what is there to prevent La Plata, which can boast of the riches of Copiapo, Potosi, and Famatina, from rivalling her neighbour in wealth, population, and national importance?

The Argentine Republic is divided into fourteen provinces, and extends southwards from the Tropic of Capricorn to the 40th parallel of latitude. Roughly speaking, the characteristics of the country admit of a two-fold division; the northern and eastern provinces being metalliferous, and the southern and littoral provinces agricultural. The latter term must, however, be accepted with some qualification, inasmuch as the cereals hitherto produced have been very scanty, and to this day the Republic is an importer of flour. In truth, the natural pasture is so abundant, and alfalfa or lucerne thrives so luxuriantly, that stock-farming is practised almost to the exclusion of all other branches of agriculture.

Major Rickard remarks that mining in La Plata is at once in its infancy and in its old age. An instance of this anomalous state of things may be seen in Mendoza, where the ancient silver mines, El Rosario and San Rumaldo, which were discovered as early as 1638, are again in active operation. The old miners dealt merely or chiefly with what Spaniards term "warm metals" (*metales calidos*), that is, those which could be reduced directly by means of mercury, and this, therefore, left for a later generation the "cold metal" (*metal frio*) which required for its reduction the process of smelting. Silver mines are not by any means confined to the province of Mendoza. In San Juan (where civil war and revolution have long been fatal barriers to all industrial progress) the district of Tontal, on the slopes of the great Andine range, is peculiarly rich in argentiferous lodes; ordinary samples from the Mine Señor containing not less than 160 ounces to the ton, and first class samples yielding 400 ounces. But, in the opinion of Major Rickard, the silver mines of Famatina, in the more northerly province of La Rioja, are the richest in the whole country. That the difficulties in working them are formidable may be gathered from the fact that some are situated 13,000 feet above the sea-level, and that the whole district is deficient in fuel of any sort, and exposed during three months of the year to a rainfall so heavy as to compel the miners to suspend their labours. In the province of Catamarca copper is the predominant metal, and in union with it an appreciable percentage of gold and silver has been found. During the year 1868 the Restauradora mine produced 2,639 tons of ore, containing by assay 506 tons of fine copper; but it must be remembered that the prevailing systems of smelting are by no means perfect.

More than one auriferous district exists within the limits of the Republic, and those which are respectively named Gualilan and Guachi (from *Gua*, which in the Huerpe tongue signifies gold) have for many years enjoyed considerable celebrity. Both of them largely enriched their first workers, and there can be little doubt that thousands of tons of ore still exist in the old workings which have been abandoned, partly from natural difficulties, but principally from the want of skilled labour.

As to the other productions of the Republic, it is impossible in this brief notice of a copious volume to do more than mention them by name. Mendoza and San Juan possess silver-lead mines of considerable extent; and in the former province petroleum springs have been recently discovered. In Santiago del Estero large tracts of land are covered with indigenous indigo; rice and tobacco are cultivated in Tucuman, and in the most northerly provinces of Salta and Jujuy are thriving plantations of coffee.

After making every allowance for Major Rickard's natural enthusiasm, it must be admitted that the country whose resources he has so minutely described, offers many and great inducements to the British emigrant to give it a fair trial. President Sarmiento desires especially to attract a further immigration of our fellow countrymen, for he infers from the success they have already achieved in the cultivation of the Pampas, that their energy and enterprise will be invaluable in developing the mineral resources of the Republic, and that Anglo-Saxon coolness and perseverance will form a favourable counterpoise to the opposite characteristics of the Hispano-American race.

C. J. ROBINSON

OUR BOOK SHELF

An Elementary Course of Hydrostatics and Sound. By Richard Wormell, M.A., B.Sc. Fcap. 8vo, pp. viii. and 146. (London: Groombridge and Sons, 1870.)

THIS little book is "designed for the use of schools, colleges, and candidates for University and other examinations." In such a work it would of course be out of the question to look for novelty of matter: by the nature of the case, to praise the author's originality would be to cast a doubt on his accuracy; and, while inaccuracy would be inexcusable, no merit can be claimed for its opposite. Hence, in trying to form an estimate of a book like this, we are inevitably led to consider whether the subjects treated are arranged in a simple and natural order; whether the exposition of principles is clear and logical, the really fundamental matters being kept constantly and prominently before the student's mind, and special consequences and applications grouped about them in such a manner as to show distinctly their mutual connection and dependence: whether, in short, the book is scientific in treatment as well as in subject. We are sorry to say that, in these respects, our judgment of the work before us is by no means favourable. We should expect a student, instead of acquiring from it ideas which are capable of growth and expansion within his own mind, and being led towards the conception of the organic connection of all scientific truth, to conclude that science—or at least hydrostatics and acoustics—consists of a series of propositions which it is his duty to "get up" and write out on the first opportunity in answer to examination-questions. The least satisfactory parts of the book are the explanatory and descriptive portions, and especially the twenty-two pages at the end devoted to sound. The author says in the preface that "the whole contains all that is required on these subjects [hydrostatics and sound] for the B.A. and B.Sc. degrees of the University of London." If this is true as regards the latter subject, it is more to the discredit of the University than to the credit of his book.

Studien über das Central Nerven-System der Wirbelthiere. Von Dr. Ludwig Stieda, Prosector in Dorpat. (London: Williams & Norgate.)

DR. LUDWIG STIEDA is already well-known for his admirable papers on the central nervous system of osseous fishes, birds, and some mammals. The present work embraces a description of the central nervous system of the frog, rabbit, dog, cat, mole, and mouse; an account of the course of the fibres in the spinal cord of Vertebrata generally; a comparison of the brain of the various classes of Vertebrata with that of man, and finally, a comparison of the cerebral with the spinal nerves. Of the description of the brain and spinal cord of the several mammals mentioned above we need say nothing here, except to remark that the account is full and carefully drawn up; the minutest structure of the several parts being given as well as their coarser anatomical features. In regard to the brain of the frog, the parts of which have received such different names, Dr. Stieda gives the following description of the organ as it appears when viewed from the upper surface. The cerebrum presents the following parts in successive order:—1, the medulla oblongata; 2, the cerebellum; 3, the lobus opticus, with its median furrow; 4, the lobus ventriculi tertii (thalami optici of authors); 5, the lobi hemisphærici, each of which terminates anteriorly in a knob constituting the tuberculum olfactorium. On the under surface of the brain there appear successively from before backwards:—(1) the bases of the lobi hemisphærici; (2) the chiasma of the optic nerves, which last proceed from (3) the lobus opticus, and between which is situated (4) the hypophysis cerebri, and behind this (5) the base of the medulla oblongata. M. Stieda then gives a full description of these parts, and of the various cerebral nerves in the frog. To this succeeds a very good general view or *résumé* of the anatomy of the brain in mammals. We may draw attention to some remarks made in the section where a comparison is made between the brain of man and that of the several classes of Vertebrata. It may be premised that little difficulty is experienced in discovering the homologous parts of the central nervous system of man and the more highly organised mammals. In the birds, however, there are several parts that are difficult to decipher; whilst in Amphibia, and still more in fishes, the nature of the several parts has given rise to much discrepancy of opinion between different observers. Dr. Stieda refers to his former work for the brain of fishes. In regard to Amphibia and reptiles, he considers that the lobi hemisphærici, or anterior lobes, being hollow, and containing a ventricle, are clearly the analogues of the cerebral hemispheres of man. The azygous portion of the central cavity, between the posterior parts of the hemispherical lobes (or ventriculus communis) in the frog, is the indication of the primordial single cavity of the first cerebral vesicle, and consequently establishes the transitional stage between the osseous fishes and the higher Vertebrata. The succeeding segment constituting the lobus ventriculi tertii, (or Zwischenhirn) corresponds in its upper part to the thalami optici; in its lower to the tuber cinereum and lamina cinerea. The third segment, or lobus opticus, agrees exactly with that of fishes, both in its external and internal relations, whilst reptiles exhibit the intermediate type between fishes and birds. Of the nature of the cerebellum there can be no doubt. In regard to birds, he observes, that the great club-like segment of the cerebrum of birds corresponds to the hemisphere of man, the bodies enclosed in them to the corpora striata, the radiated septum to the septum pellucidum. He considers the existence of parts analogous to the corpus callosum and fornix of man to be doubtful. The succeeding segment corresponds to the optic thalami; the large spheroidal body of the lobus opticus to the corpora quadrigemina. Two plates accompany the treatise, which are devoted to the histology of the parts described. H. P.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

The Difficulties of Natural Selection

As Mr. Bennett complains that I have charged him with errors he has not committed (which I should much regret to have done), I must ask permission to justify my statements by a reference to his own words.

1. Mr. Bennett says that he is unable to discover where he has led his readers to understand that there is only one completely mimicking species of *Leptalis*. I will therefore show him where he has done so. In the third column of his article (p. 31) he says: "Another South American genus of Lepidoptera, the *Leptalis*, belongs structurally to an entirely different class, the *Pieridæ*, and the majority of its species differ correspondingly from the *Heliconidæ* in their size, shape, colour, and manner of flying, being nearly pure white. There is, however, *one particular species* of *Leptalis*, which departs widely in external facies from *all its allies*, and so closely resembles a species of *Ithomia* as to deceive," &c. &c. Then comes the argument and the mathematical calculations always referring to "the *Leptalis*," and it is at the end of this, at the bottom of the next column, that we have the following passage (of which Mr. Bennett in his reply has only quoted a line and a half): "For supposing the chance is reduced from one in ten million to one in ten thousand, and it is said that the world has existed quite long enough to give a fair chance of this having occurred once, it is not a solitary instance that we have. Mr. Bates states that in a comparatively small area several distinct instances of such perfect mimicry occur, Mr. Wallace has a store in the Malay Archipelago, Mr. Trimen records several of wonderful completeness in South Africa," &c. Now, as there is not a word here about other species of *Leptalis*, but only about other cases of mimicry, as *Leptalis* is unknown in Africa or the East, as mimicry occurs in other genera and families of Lepidoptera, and other orders of insects, and as Mr. Bennett has himself stated, that the "*one particular species of Leptalis* departs widely in external facies from *all* its allies," I think it will be admitted that I was justified in asserting that Mr. Bennett's readers would be "led to understand," that there was only one species of completely mimicking *Leptalis*. If I was not so justified I confess my ignorance of the English language, and beg Mr. Bennett's pardon.

2. I leave your readers to judge for themselves whether the fact of a *Leptalis* having twenty offspring does or does not affect the mathematical argument as set forth by Mr. Bennett; but when, in answer to my statement, that the right variation has, by the hypothesis, a greater chance of surviving than the rest, he asks: "By what hypothesis? The hypothesis that these small variations are useful to the individual, the very hypothesis against which I am contending as unproved,"—I must protest against his denying his own words. For, at p. 31, col. 1, he says: "The next step in *my argument* is, that the smallest change in the direction of the *Ithomia* which we can conceive, on any hypothesis, to be beneficial to the *Leptalis* is, at the very lowest, one-fiftieth of the change required to produce perfect resemblance;" and six lines farther on, "For the sake of argument, however, *I will suppose* that a change to the extent of one-fiftieth *is beneficial*," and then comes the calculation. Again, I must acknowledge my ignorance of the meaning of words if Mr. Bennett does not here directly contradict himself. I never said the hypothesis was proved, but only that Mr. Bennett's argument, founded on it, was unsound, and for the sake of the argument he had admitted the hypothesis.

Mr. Bennett goes on to say: "The new factor, of which I take no account, is, again, entirely dependent on the admission of the natural selectionist premiss." This new factor is the principle of *heredity*. As he acknowledges that he takes no account of it, we must presume that he denies its existence; and as the whole of Mr. Darwin's theories and my own fall to the ground without it, he might have spared himself the trouble of his "mathematical demonstration."

3. I do not consider, as Mr. Bennett seems to do, that the distinction between "protective resemblance" and "mimicry" is a subtle one. Anyone who reads his paragraph on this subject (p. 32, col. 2) will, I think, be under the impression, as I was, that he alluded to mimicry, or mimetism, properly so called, as being strongly developed in birds. It seems, however, that he means only protective resemblance; but this, I believe, to be equally common among the very lowest forms of life. Transparency, for example, is a great protection to aquatic animals, and it is very prevalent in low organisms. Fishes are all, or almost all, protectively coloured, by the back being dark and the belly light, so that, whether looked at from above on the dark background, or from below on the light one, they are equally difficult to see. In many fishes, too, we have a specific protective resemblance as perfect as in any birds (see "Contributions to the Theory of Natural Selection," p. 55), and this is as much opposed to Mr. Bennett's theory as the absence of true mimicry in birds and mammals.

4. Mr. Bennett says, I have "brought no evidence to show that *extremely small variations* afford any immunity from the attacks of enemies,"—but this was quite unnecessary, because I show that the variations which continually occur in insects are by no means "extremely small." He also says that I "give no explanation of the tendency of the *Leptalis*, referred to by Mr. Bates, to produce naturally varieties of a nature to resemble *Ithomiæ*." But Mr. Bates introduces this remark with—"It would seem as if;" and though I think that the fact may be so,

and that it is not difficult to explain, yet I do not feel bound to explain every supposed fact as if it were a well-established one. As to the "parallelism of the development of protective resemblance and of instinct in the animal world," which I am also asked to explain, I deny that it has been proved to exist.

In conclusion, I will observe that the theory of Natural Selection, and its subordinate theory, Mimicry—have now been so fully developed by Mr. Darwin, Mr. Bates, Mr. Trimen, and myself, that I conceive it to be a full and sufficient answer to any opponent if we can show that his particular objections are unsound. This, I believe, I have done in the case of Mr. Bennett, although I am sorry to find that he cannot see it, and it is therefore unnecessary to go fully into the collateral points on which he has touched, and which have already been sufficiently explained by Mr. Darwin or myself.

ALFRED R. WALLACE

I AM forcibly reminded of Pope's lines,

> A little knowledge is a dangerous thing:
> Drink deep, or taste not, the Pierian spring,

by the argument used by Mr. Bennett in the P.S. to his letter in NATURE, of the 24th November, in which he says, after quoting a passage from a paper by Mr. Jenner Weir: "Here at least it would seem as if *imperfect* mimicry was anything but beneficial to the individual; how can the principle of natural selection account for its propagation in these instances?" He considers that a little mimicry is a dangerous thing. I would rather agree with Lord Brougham in his remark on the above lines, that as a little knowledge is better than great ignorance, so a little mimicry is better than great dissemblance.

But the case referred to by Mr. Jenner Weir is plain, and the argument, instead of being against the theory of natural selection, is really in its favour.

Some of the larvæ in question, for some reason of which we are unaware, are not so palatable to birds, and they, therefore, are not eaten by them to the same extent. These larvæ have not so much need of the aid of protective resemblance, and indeed their hair, spines, and gay colouring are advantageous to them instead of a drawback. The smooth-skinned larvæ require the aid of protective resemblance for their preservation, but no one would for a moment expect that because an insect has a protective resemblance to the place on which it rests, that every individual is to escape destruction by its enemies.

Mr. Bennett again asks for an explanation of the tendency of the South American *Leptalidæ* to resemble *Ithomiæ*. I think the reason is clear. Mr. Bates, in his paper, read before the Linnean Society in 1862 (Trans., vol. 23), states that the *Leptalidæ* are exceedingly rare compared to the *Heliconidæ*, and that the proportion is about 1 to 1,000, and also that none of the *Leptalidæ* are found in any other locality than those of the *Heliconidæ* they mimic. From this I should judge that the *Leptalidæ* cannot make head against their enemies, and require the assistance of mimicking some better protected species to be able to maintain itself.

November 25 S. N. CARVALHO, JUN.

PROFESSOR HUXLEY has referred Mr. Bennett to the highest authority for an answer to his reasoning on a difficulty in the theory of natural selection. Meanwhile, Mr. Wallace has replied on his own account. Upon the biological question I do not presume to touch, but I wish to say a word upon the mathematical one, especially as I cannot think Mr. Wallace has really met this part of the argument.

Mr. Bennett's argument is shortly this. A modification must be advantageous before natural selection can take hold of it. In order to be advantageous, it must not be too small; it must be so great as to be attainable only in the course of many generations, during which, in the absence of natural selection, we must see whether chance will carry us over the ground. As an extreme concession, he supposes that an advantageous *amount* of change might be accumulated in twenty steps; and, assuming that the required *direction* of change is only one out of twenty directions equally probable, he easily shows it to be violently improbable that a stationary population of one million should produce a single instance of even ten such steps in successive generations.

But why is it necessary to suppose the steps made in successive generations? Provided that the required number are made within reasonable time, it may surely be immaterial what intervals of merely unprogressive variation may elapse between them. In 200 generations, the first, fifteenth, fiftieth, for instance, and seventeen more, might make steps in the right direction, and all the rest might make steps in some or all of the other nineteen possible directions. Ten would in fact be the most probable number of steps in the right direction, and it would be about an even chance that there were ten at least.

However, as soon as we suppose steps in other directions, we must allow for the possibility of steps which shall actually reverse such progress as might be made in the right direction. If one change out of twenty equally likely is in the right direction, there will be on an average one in the opposite direction, and eighteen in indifferent directions. If we assumed that, in 200 generations, 180 were neutral, while twenty made steps forward or steps backward, these twenty *might* be all forward, and the chance that they were so would be one in 2^{20}, or one in little more than a million. Generally, the number of neutral steps would be a little more or a little less than 180, and if we allow for this the resulting chance will be considerably increased. Several instances would probably be produced by a population of a million; and I presume it is easy to allow much more than 200 generations of butterflies.

Dr. Nicholson's "Zoology"

I NOTICE in NATURE for Oct. 20, a review by Mr. E. Ray Lankester, of a Manual of Zoology recently published by me, and I crave a small portion of your space to say a few words thereon. Upon Mr. Lankester's zoological strictures on my work I will not enter, partly because the public verdict on the merits of my work has already been very emphatically and decisively expressed; partly because the sins laid to my charge are chiefly of *omission* and not of *commission*, and are, therefore, more or less inevitable in a work of such limited compass; and partly because it must be patent to everyone how much more admirably the work, unfortunately left to me, would have been discharged by Mr. Lankester himself.

In the matter of *Greek*, however, Mr. Lankester really must excuse me if I decline to bow to his superior knowledge. I am well aware that he probably entertains a fresher recollection of his school days than I can boast of, and I might, therefore, without shame, have pleaded guilty to some obliviousness of Greek roots. Mr. Lankester, however, has been singularly unlucky in the point of attack chosen by him. He takes upon himself to condemn the whole of the glossary to my work, because he finds the *twelfth* word of the same ("actinomeres") derived from the Greek word *aktin*, and he is good enough to add the information that "there is no such Greek word as *aktin*." Now, any decent lexicon would have informed Mr. Lankester that *aktin* is not only good Greek, but that it is the original form of the word, and that *aktis* was employed for the first time by Pindar, not, therefore, till about 450 B.C.

In conclusion, if I may be permitted to make a suggestion, I would recommend Mr. Lankester, in his capacity as critic and appraiser of the work of other men, not to judge in future of the value of a haystack by the first straw that he may happen to pull out of it; or, if he must do this, to be very sure before giving his opinion to the public, that it *is* a straw that he has succeeded in laying hold of.

Newhaven, Edinburgh H. ALLEYNE NICHOLSON

DR. NICHOLSON'S extraordinary assertions as to the supposed word "aktin" really demand no serious discussion, which, indeed, would be out of place in NATURE. A reference to Liddell and Scott's Lexicon will conclusively demonstrate to any person interested in the matter that he is entirely wrong. The following additional blunders in Dr. Nicholson's glossary will enable your readers more fully to judge of his accuracy, and it will require considerable boldness to attempt to justify them by reference to imaginary archaic forms:—1. In several places we find Dr. Nicholson giving "poda" as the Greek for "feet," a gross grammatical fault. 2. "Pseud*os*" is given as the adjective corresponding to the English word "false." 3. "Enchuma" is said to be a Greek word meaning "tissue." It has not this meaning. Dr. Nicholson's mistake arises from ignorance of the origin of the signification of the word "parenchyma." 4. "Laima" is given in several places in the glossary for "throat," in place of "laimos."

It is improbable that these are anything but a fraction of Dr. Nicholson's etymological misrepresentations. Mistakes in the glossary of a zoological work are not of very great importance, and would not in this case have demanded notice had they not been fair samples of the general character of the book in which they occur.

I much regret that the fact of the writer's name being appended to the notice of Dr. Nicholson's work should have led him into the region of personalities, whither I do not intend to follow him. E. RAY LANKESTER

Glass Floats off the Isle of Lewis

IT would be of great importance if the *fact* could be ascertained whether the floats are from the Norwegian or from the Canadian fisheries. Your note of November 10 says, "They are hermetically sealed, and have certain characters, such as IV. or VI., impressed on the sealed part." Doubtless your columns are read in Norway as well as in Canada, and possibly a correspondent, from these characters or from other evidence, may claim the floats for one or for the other side of the Atlantic. In favour of the *west* side, but with the utmost deference to the opinion of Mr. Gwyn Jeffreys, I suggest that a north-*east* wind is an unlikely conveyance to "the *west* side of the Island of Lewis," or to "the *western* coast of Shetland."

A writer in the *Athenæum* of this week (Nov. 19, p. 659) thinks that these "net floats" are carried to Nova Zembla, and "still farther to the north and east" by the Gulf Stream. Dr. Carpenter supposes a constant warm surface current from each tropic to each pole, and a constant cold current below from each pole to each tropic, caused as we cause the currents of water to warm our houses. Suppose this grand theory to be true. The surface current should warm east coasts as well as west coasts. The same parallel touches England, Newfoundland, and Vancouver's Island. The climate of England and of Vancouver's Island on west coasts is "insular." The climate of the *island* of Newfoundland on an east coast is "excessive." This difference of climate in islands, on the same parallel, at the same levels, results from currents of *air*, not from currents of *water*—namely, from the prevalence of south-west winds in the north temperate regions. In winter with a south-west wind we hunt, with a north-east wind we skate.

GEORGE GREENWOOD, Colonel

Brookwood Park, November 19.

ENGLISH GOVERNMENT ECLIPSE EXPEDITION

THESE arrangements and instructions are not yet finally completed, but it is thought that the latter may be useful to members of other Expeditions, though they are not yet by any means complete.

A. SPANISH AND ALGERIAN PARTY.

NOTE.—*This party leaves Portsmouth in the "Urgent," on the 6th proximo. Observers to be on board by* 5 P.M. *on the 5th.*

1. *Cadiz Detachment.*—In charge, the Rev. S. J. Perry. Spectroscope, the Rev. S. J. Perry and assistant (Mr. Hostage), Mr. Abbay; Polariscope, Mr. Moulton, Mr. Hudson: Sketches of Corona, Mr. Naftel, Mr. Smyth, Mr. Penrose, Mr. Collins; Time and General Observations, Captain Toynbee.

2. *Gibraltar Detachment.*—In charge, Captain Parsons. Spectroscope, Mr. Carpmael, Mr. Gordon; Polariscope, Mr. Lewis, Mr. Ladd; Photography, Mr. Buckingham, and assistant (Mr. Spiller); Sketches of Corona, Mr. Hunter, two Oxford men; Saturn in the Corona, Mr. Talmage, Mr. Maclear; Chemical Intensity, Mr. Thorpe.

3. *Oran Detachment*—In charge, Mr. Huggins. Mr. Huggins, Admiral Ommanney, Rev. F. Howlett, Mr. Carpenter, Mr. Crookes, Captain Noble, Dr. Gladstone, Prof. Tyndall.

B. SICILIAN PARTY.

NOTE.—*This Party leaves London, overland, at* 8.45 P.M. *from Charing Cross, on the 7th proximo.*

In charge, Mr. Lockyer. Spectroscope, Mr. Lockyer and assistant (Mrs. Lockyer), Prof. Roscoe and assistant (Mrs. Bowen), Mr. Seabroke and assistant (Mr. Burton), Mr. Pedlar; Polariscope, Mr. Raynard, Mr. Griffith, Mr. Clifford; Sketches of Corona, Mr. Brett, Mr. Darwin; Photography, Mr. Brothers, Herr Vogel, Mr. Harris; Time and General Observations, Mr. Vignoles, Sen., Mr. Vignolles, Jun.

INSTRUCTIONS TO OBSERVERS.

Instructions for the Polariscopic Observations of the Corona, including Beams and Streamers.—It is recommended that the polariscopic examination of the Corona be carried on as follows:—

1. To examine a detached and selected part of the Corona about 6′ from the limb of the sun, and say about 8′ in diameter. 2. A field extending from the limb of the sun outwards should be examined either with a Nicol's prism, or a double image-prism. 3. The light of the streamers at some distance from the sun should be examined with a Nicol and a crystal. 4. The polarisation of the Corona should be examined in such a manner as to eliminate atmospheric polarisation. *Note.*—The most suitable instruments for ascertaining the plane of polarisation, and the proportion of polarised to unpolarised light are (1) a double-image prism; (2) Savart's polariscope; (3) a plate of quartz, consisting of two compensation wedges turned through an angle of 180°; (4) a plate of arragonite, or calc spar, cut perpendicular to an optic axis, and affixed to an analysing prism; (5) a polarimeter, consisting of four plates of glass, movable on an axis perpendicular to the plane of polarisation.

First Observation.—The object of this observation is to observe the polarisation (if any) of the Corona without having the observer's attention distracted by the chromosphere. A Savart's polariscope is recommended by preference. The Nicol's prism of the polariscope should be set beforehand with its principal plane (or plane of symmetry) radial, *i.e.* perpendicular to the sun's limb, and the observer must note whether bands are visible, and if so, whether they are black-centred or white-centred. Should the bands be feeble, it will be well to rotate the polariscope, prism and plates of course moving together, and quickly restore it to its primitive azimuth, after having noted the estimated azimuth of the Nicol when the bands are strongest and black-centred. Should no bands, or only dilute bands be seen, it may be that the Corona, though polarised, is overpowered by other light; and the observer will move the telescope from the sun, radially if it may be, if in any other direction rotating the polariscope so as to render its principal plane radial in the new position. He will then note whether, though the light becomes feebler, the bands become less dilute. Should, on the other hand, the bands be strong, the observer, after having satisfied himself as to the plane of polarisation, will endeavour to make out whether by means of the polarisation of its light the Corona can be detected superposed on the chromosphere. He will, therefore, move the telescope *towards* the sun, keeping the principal plane of the polariscope radial, and note how near the sun the bands can still be seen. To provide for the contingency of this observation, it will be well to point in the first instance to the side of the sun which will be first uncovered. If time permit he should try whether there is any sensible quantity of polarised light on the dark disk of the moon, rotating the analyser and determinating the plane of polarisation.

Second Observation.—The special object of this observation is to differentiate, if possible, between the Corona, on the one hand, and the Chromosphere, or whatever else may be self-luminous (be it even a portion of the Corona itself), on the other. This will be possible if the light of the Corona be strongly polarised, so as to admit of comparative extinction by an analyser. The observer should turn the analyser so as to extinguish, as far as may be, the light of the Corona in the neighbourhood of a radius depending on the angular position of the analyser. He should notice the form, colour, and general appearance of any residual luminosity other than the well-known protuberances; should contrast the appearance, especially as to colour, with that seen when the light is analysed so as to retain light from the same region polarised in the perpendicular direction, and should ask himself whether the luminosity is such as could be accounted for by the superior brightness near the sun of the unanalysed light, even though it were to suffer the same proportionate loss by analysis as the Corona at a greater distance. Of the instruments named the Nicol's prism is better adapted for a general survey, not requiring any limitation of field; the double-image prism is better adapted for a comparison of the oppositely polarised images, since the observer can compare them *directly*, not one with *his memory* of the other. The double-image prism will require a diaphragm with a long and moderately broad aperture in the focus of the eyepiece, rotating with the prism, and in the observation the length should be placed in a radial direction.

Third Observation.—The observation of the streamers as to polarisation might throw much light on their nature, and the observer who undertakes this observation, by means of a Savart's polariscope, or else of a Nicol's prism capped with a plate of calc spar or arragonite, will be in a condition to determine with advantage the plan of polarisation, if there be polarisation, of the Corona generally. But the streamers must be his first object.

Fourth Observation.—It has been supposed by some that the polarisation observed in the Corona was really due to the *secondary* illumination of the intervening portion of the Earth's atmosphere, in other words, to the illumination produced by reflection from clouds, &c., towards the horizon. This effect may be eliminated by using a Savart's polariscope, or, better, a polariscope with quartz wedges, and turning the instrument till the bands (if any) seen on the moon's disc disappear. The corona can then be scrutinised as to polarisation, and the polarisation examined in different azimuths of the Nicol's prism relative to the radius drawn from the sun's centre, by pointing the telescope instead of rotating the analyser. In this observation the observer has the choice of two rectangular azimuths of the polariscope, for each of which the bands (if any) on the moon disappear, and if no bands be seen on the moon he is free to scrutinise the polarisation of the Corona, by turning the polariscope.

General Remarks.—The object-glasses of all telescopes intended to be used in polariscopic observations should be examined before departure as to their freedom from defects of annealing. All polariscopes including a Nicol's prism, or tourmaline, should be marked, so that the principal plane may be readily known *by feeling*, as sight-marks might fail for want of light. Double-image prisms should have one side of the aperture in the diaphragm marked so as to distinguish the two images.

Instructions for the Spectroscopic Observation of the Chromosphere.

Note: The objects to be obtained are:—1. To determine the actual height of the chromosphere as seen with an eclipsed sun; that is, when the atmospheric illumination, the effect of which is doubtless only partially got rid of by the Janssen-Lockyer method, is removed. If the method were totally effective, the C line, the line of high temperature, should hardly increase in height; but there can be little doubt that the method is not totally effective, so the increase in height should be carefully noted. 2. To determine if there exists cooler hydrogen above and around the vividly incandescent layers and prominences. To do this the band of the spectrum just above the stratum which gives the hydrogen lines before totality and during totality, should be carefully examined, to notice (*a*) if any traces of the hydrogen spectrum exist above the region which before totality gave the hydrogen lines, and (*b*) what lines extend outside the hydrogen spectrum and whether they also exist with it in the lower strata. 3. To test the American observations of last year as to the existence of a line at 1474 in the corona spectrum, by seeing if it be visible above the region which gives the hydrogen spectrum. 4 To determine whether any other gases or vapours are ordinarily mixed up with hydrogen, but remain invisible with the uneclipsed sun in consequence of the absence of saliently brilliant lines in their spectra. The observations should be conducted as follows:—1. Work with a horizontal slit, or a slit in a parallel of declination, according to the instrument used, whether altazimuth or equatoreal. 2. See that the spectroscope telescope works easily, so that sweeping along the spectrum is easy. 3. Find before totality an average plain-topped region of the chromosphere, where some motion on either side does not brighten, or thicken, or lengthen the lines near the part covered at the commencement of totality. 4. Observe this before and during part of totality, the telescope being driven by the clock if an equatoreal is used. 5. Just before totality sweep from red to violet; note the lines and their lengths; mark the 1474 line and the lines between D and E carefully. 6. Immediately after the commencement of totality sweep back; note new lines—their heights; especially the comparative heights of C, near D, F, and near G, with these former heights; and especially whether band over *b*, and the thickness of F. Note also the lines between D and 1474. 7. Just before the end of totality unclamp and bring back the slit to the *following* limb of the Moon; and note the extinction of the spectrum by the reappearance of the Sun, if possible by a rapid sweep; if this is not possible, then watch the behaviour of F; sweep back again to see if there be any variations from (5) in the new region now observed. 8. Carefully note position angle where slit cuts limb. 9. Record the impressions of facts, and facts not already noted, as soon as possible.

Instructions for the Spectroscopic Observation of the Corona

Note.—*The word Corona is here used for convenience, to include all the light above the prominences. It therefore includes that part of the chromosphere which is generally veiled to us when observations are made by the Janssen-Lockyer method.*

The principal object to be obtained is:—To determine whether it is possible to differentiate the outer layers of irregular outline and streamers from a stratum say some 5′ or 6′ high round the sun, which may possibly be the limit of the gaseous envelopes above the photosphere. To attack this question, we require a long slit, a large aperture, and long collimator, and small dispersive power. The slit must be adjusted for a faint cloud before totality, and on no account is it to be touched before observations of a similar cloud can be made after totality, by the heads of the party. The most important observation to make is, whether there are any dark lines in the spectrum at any distance from the sun; and if so, at what distance? Next, whether there are any bright lines; if any, their positions must be noted, especially if the lines recorded by the American observers are again visible. The observations should be conducted as follows:—1. Arrange the instrument so that the image of the following limb of the moon, at the point of its first contact, will fall on the left-hand side of the slit, placed nearly horizontally. 2. See if Corona is visible before totality, and note its spectrum with utmost care, moving the slit in azimuth, so that perhaps, at the instant during totality, while possibly with a long slit, the spectrum of the sun or prominences on the preceding limb is visible in the same field of view.

Some Particulars to be Especially Noticed by those Observers who make Drawings of the Corona

1. Its extent, and the boundary-line *if any;* if no definite boundary, this *should be stated.* 2. Whether

there is any change, all changes must be most carefully shown in any manner the artist may prefer. 3. Especially note all long streamers. 4. All tints and change of tint, and whether the colour is distributed in patches or in layers concentric with the moon, or in connection with the prominences. 5. Whether it consists of a level patch of luminous haze or radiating beams of light, or of bundles of hyperbolic rays. 6. If of radiating or hyperbolic beams, whether they are evenly distributed all round, or in groups only. 7. Whether the dark intervals between such radiating beams are constant or fluctuating. 8. Whether it is concentric with the moon. 9. Whether it is equally intense all round the moon. 10. Whether the outer border exhibits any coruscations, or whether its definition is permanent and equally pronounced all round. 11. Whether the light of the Corona is more intense or less so in the immediate neighbourhood of the prominences. 12. How much darker the moon's disc is than the sky.

ENERGY, AND PROF. BAIN'S LOGIC

[EXTRACT FROM PROF. TAIT'S OPENING ADDRESS TO THE UNIVERSITY OF EDINBURGH, NOV. 2, 1870]

THE so-called *Laws of Motion* first explicitly stated, as we now employ them, by Newton in the Principia, are partly due to Galileo, partly to his immediate successors. Like all great physical discoveries, they were more or less clearly seen by many philosophers about the time in which Newton threw them into the simple, and yet comprehensive, form in which we now use them. As ordinarily understood, they embrace the results of observation and experiment as to the action of force on matter. The first tells us how matter behaves when not acted on by force, and therefore shows us how to *detect* the action of a force. The second tells us how to measure the force by its effects, and how to calculate the action of a force or forces acting on a mere *particle* of matter. The third, as directly interpreted, shows how to apply the other two to the motion of masses or of groups of particles. With these alone we have the foundation of an enormous portion of the science of Dynamics, and we require merely a sufficiently powerful mathematical process to enable us to develop to their utmost the calculations necessary for the determination of equilibrium or motion of any set of masses whatever, so long as the motion is visible, or capable of being rendered visible by a microscope.

But we require something more before we can extend mathematical calculations—which, be it ever remembered, are necessary in physics solely on account of the imperfections of our intellect; merely saving us an intolerable amount of thought which would otherwise be wasted on petty details—something more, I say, is required before we can apply our mathematics to Heat, Electricity, Chemical Action, &c., &c.

Curiously enough, that something was foreseen and provided for by the keen intellect of Newton. He gave it in the form of a *second* mode of interpreting his third law, quite distinct from the ordinary one, which is the well-known assertion that "Action and Reaction are equal and opposite." Instead of using the terms Action and Reaction in the sense of mere pressures or tensions, he shows that the law will equally hold if they stand for what are now called rates of *spending* or of *receiving* energy; or, in more familiar language, rates of doing work. So that whenever there is transference of energy from one body to another, the one gains *exactly* as much as the other loses. This is at present the grandest physical law known. That we may understand it better, let us take first a simple physical fact, but one of a somewhat analogous nature. It is a comparatively recent discovery that *matter is indestructible*, yet so important that without it we may be certain that chemistry could never have become a science. If a chemist were not assured by experiment that no quantity of matter, however small, is ever put out of existence, submit it to what ordeals he may, what confidence could he have in the results of an analysis? Or again, where would his science be if new matter could suddenly make its appearance? The balance is his most important instrument, but without the confidence (derived from experiment) that matter cannot change in quantity, its indications would be of no value to him.

So it is, but in a more extended sphere, with the Natural Philosopher, and it is a source of legitimate pride to us, that as Newton first hinted at this grand modern generalisation, and first gave the mathematical method naturally fitted for its development, so it is to this country again, and mainly to Dr. Joule of Manchester, that we owe the proof (which must, of course, be *experimental* to be valid) that energy is, like matter, *indestructible*. It is, therefore, in the usual sense of the word, as REAL as matter. In fact, the physical phenomena of the Universe (excluding in the meantime, on account of our utter ignorance, some of those connected with life) depend upon matter and energy alone. Different combinations of matter constitute the subject of our chemistry; different groupings of molecules as well as of masses, and different distribution of Energy, form the rest of our Natural Philosophy. Hence the overwhelming importance of this real *something*, Energy, in the whole of Physical Science.

I shall devote the rest of my time this morning to very elementary notions connected with energy and this grand law of Nature. But before I do so I have a few words to say about another work in which the principles of Natural Philosophy are discussed; a book infinitely more likely than that of Hegel (whose absurdities I have already pointed out to you) to fall into your hands. It is now not a dreamy and dogmatic German, evolving everything from himself, and railing at physical facts as well as at exquisite methods in mathematics, with whom we have to do—it is on the contrary, a hard-headed Scotsman, and a Professor in one of our Universities. We have here no evolution from consciousness to laugh at, no sneering at experimental science; we have to guard against dangerous misconceptions of the truths discovered by physicists; mistakes all the more dangerous that they are honestly held, and that they have been assigned a prominent place in a text-book which many of you may have at some time to read; and especially because, as students, you are peculiarly liable to be led away by *ex cathedrâ* statements. For obvious reasons I cannot take many examples now; in the more abstruse, the statement itself, and the exposition of its error, would be alike unintelligible to you; in the simpler ones you may be trusted to see the error for yourselves.

The first I quote is from what is called the Logic of Physics, and is, to a certain extent, personal. "*Volume* and *mass* rightly precede *density* in order of definition. Messrs. Thomson and Tait make *density* precede *mass*." And we do so, we think, very logically, because density is a *specific* property of matter, unalterable in general, except to a very small extent, by physical processes, while volume and mass are absolutely indefinite, depending as they do upon the quantity of matter spoken of.

Again, "In the transfer of force, *nothing is lost*. The mechanical momentum transmuted into heat is fully accounted for in the heat produced: by proper arrangements it could all be gained back." The last nine words, however they may be interpreted, are essentially false: in fact they contain an explicit denial of the second law of thermodynamics upon which Sir W. Thomson based his grand law of Dissipation of Energy, one of the most important of his many splendid contributions to physics, and one having the most direct bearing upon the future of the physical universe. The rest of the statement, as it stands, is also false. It may be made correct by writing one of the words, *work*, *power*, *potency*, or preferably *energy*, in place of *force*, and also in place of *momentum*. What would be thought of a man who should say—"I paid six weeks for it," meaning "pounds" by "weeks." For "momentum" cannot be transformed or "transmuted" at all, it remains for ever unchanged.

Again, when bodies impinge on one another, "the rise of temperature is exactly proportioned to the visible momentum destroyed." Let us put the correct word "energy" in the place of momentum, and we find that this asserts the startling physical fact that the specific heat of every body is the same at all temperatures. If we take the statement as it stands without correction, it is simply nonsense.

Again, "the foot pound, meaning the force expended in raising one pound weight one foot, which is the same as a (*sic*) momentum of one pound moving at eight feet per second."

Raising one pound weight one foot is a feat which, by proper combinations of machinery, may be effected by any given force whatever, be it the weight of a grain or of a million tons. But a "foot pound," and the "momentum of one pound moving at eight feet per second" cannot possibly be compared with each other, any more than a cubic yard can be expressed as a number of square yards, or the height of a mountain in acres, roods, and poles.

You will see that the error in the examples I have just chosen (excepting of course the fatal one about restoration of energy) is in great part due to the misuse of words. Yet it is from a treatise on Logic that I have quoted!

The essence of the lesson taught by all this is simply the conviction that scientific knowledge has reached such an immense development that no one man can now possibly master thoroughly more than one or two of its many branches. There can be no "Admirable Crichtons" in our days. The greatest logician the world has produced, or is likely to produce, for many a long day, the lamented George Boole, more than once expressed his regret that a systematic logical treatment of human knowledge, even in moderate compass, and going little farther than the elements in each branch, had become absolutely impossible as the work of one man—impossible, that is, for a man who revolted at the idea of publishing anything he knew to be defective.

MOUNTAIN CLIMBING

In the number of NATURE for June 23, 1870, I described an ascent of Mount Etna which I made on March 4 of this year, with an excellent guide, Pietro Cravagna.

I now propose to make some remarks on a few points of interest with regard to mountain climbing. One of the most important of these is the alleged lowering of the internal temperature of the body under such conditions.

During two ascents of Mont Blanc made on the 17th and 26th of August, 1868, by Dr. Lortet, of Lyons, and Dr. Marcet, of London, and described by Dr. Lortet in the *Lyon Médical* of September 26, 1869, experiments made apparently with great precaution on Dr. Lortet himself with a registering maximum thermometer (of Walferdin), by which (between $+30°$ C. and $+40°$ C.) hundredths of a degree could be appreciated, showed that the internal temperature of the body under such conditions is lowered to a very remarkable extent.

I will quote Dr. Lortet's own words: "A jeun et exactement dans les mêmes conditions, *pendant la marche*, la décroissance de la température intérieure du corps est très-remarquable, *elle est à peu près proportionelle* à l'altitude à laquelle on se trouve."

In effect, from the table given in the paper referred to, I find that during the first ascents the internal temperature descended *gradually* from 36·3° C. (that *during exercise* at Chamounix, 1,050 metres above the sea) to 32° C. at the summit of Mont Blanc (4,810 metres above the sea); while during the second ascent the difference was from 35·3° C. to 31·8° C.

Dr. Lortet found that as soon as he stopped for a few minutes, the temperature of his body rose briskly to the normal standard, except on the summit itself, where "il a fallu près d'une demi-heure pour que le thermomètre atteignît sa hauteur habituelle."

During digestion, in spite of the exercise being taken, the temperature remains normal, or even rises; but this does not last long: "Une heure à peine après avoir mangé, le corps se refroidit de nouveau par les efforts." The descent of the temperature of the body under such conditions, then, amounts sometimes to more than 4° C.; and if we take the difference between the normal temperature of the body *at rest*, and that observed by these experimenters on the top of Mont Blanc, the difference amounts in one case to 5° C., "abaîssement énorme pour les mammifères dont la température était reputé constante!" as Dr. Lortet justly exclaims.

Now Mount Etna is particularly suitable for such experiments; one begins to walk either at Nicolosi, or preferably at the Casa del Bosco, and one has nothing to do but to go straight up; there is nothing in the way, it is simply a long "grind" of some five or six hours or more, according to the state of the snow. A series of misfortunes with my maximum thermometers prevented my repeating the above-described observations, and I have referred to them at such length in the hope that some one may be induced to take the excellent opportunity afforded by the expedition to Sicily of deciding so important a point.

The state of the circulation is hardly less important than that of the internal temperature.

Dr. Lortet found that the pulse increased in frequency from 64 per minute at Chamounix to 172 on the summit of Mont Blanc, and he was further enabled, by means of the sphygmograph, to make some observations as to the *state* of the pulse at various altitudes. In ascending Etna I made some comparative observations on the frequency of my guide's pulse as compared with my own, which show some points of interest.

At the Casa del Bosco my pulse was 68, my guide's 74; we had both *ridden* to that point, and the difference is probably an illustration of the established fact that the circulation of persons living in mountainous districts is quicker than that of those living in plains. On arriving at the summit of Etna after a ride of an hour and a quarter (from the Casa del Bosco), a rest of fifteen minutes, and a stiff walk of three and a quarter hours over dry, hard, snow (an exceptionally easy ascent),* my pulse was very irregular, and about 114 or 115 to the minute, while the guide's was only 89—that is to say, that mine had increased 46 beats in frequency, his only 15; or mine was about $\frac{2}{3}$rds, his only about $\frac{1}{5}$th, as fast again; showing the slight effect of such ascents on those who are used to them, and who live habitually in mountainous countries.

But this was still more forcibly illustrated by the state of our pulses after a very quick descent, a regular trot all the way (we had stayed two hours at the summit, and eaten a hearty breakfast); at the place where we left the mules, I found that while my pulse, after a minute or two's rest, was at 106 or 107, the guide's was at 99 or 100; mine being 8 beats *less* than it was on arriving at the top, his 10 beats *more*; his circulation was *less* disturbed by

* Later on in the month of March, when much snow had recently fallen the Rev. A. G. Girdlestone and I, with two other friends, made an ascent: it took us nearly eight hours to walk from the Casa del Bosco to the Casa degli Inglesi, and we saw nothing but a very heavy snow-storm.

walking fast up the mountain, carrying a load of provisions, than by running down it with nothing to carry; mine, on the contrary, as one would expect, much more so by walking up than by running down. (Of course I could get nothing in the shape of sphygmograph at Catania.)

Dr. Lortet has recorded some interesting observations, made with the aid of the anapnograph of MM. Bergeon and Kastus, on the state of the respiration. It is much quickened, as is well known; the expiration is much prolonged, its amplitude much lessened, the inspiration shortened and quickened; much less air being inspired and expired than is normally the case.

These effects are partly due to the rarefaction of the air, less oxygen by weight being taken in at each inspiration, and partly to the excessive muscular exertion, which demands a corresponding increase in the animal heat, and so a corresponding increase in the amount of oxidation taking place in the blood; this not being always obtainable and the exercise being continued all the same, the normal temperature of the body cannot be maintained, and so it falls, and one becomes miserably cold while walking, and has to stop to get warm again.

Now as to the amount of work done; that is very much greater than is commonly supposed: leaving out of consideration the difficulties encountered in walking either over soft snow or over slippery places, especially when very steep, I find that in climbing Etna, starting as I did, on the occasion that I have already described, from some distance above the Casa del Bosco, I lifted about 150lb. to the vertical height of at least 5,700 ft., or about 380 tons one foot; adding 10 foot-tons (little enough) for the horizontal distance traversed, we have 390 foot-tons as representing work done in $3\frac{1}{4}$ hours: now 390 foot-tons is about the work done by a person of the weight above mentioned in walking 22 miles on level ground; that is to say that, without making any allowance for the increased difficulty of breathing due to the rarefaction of the air or for any of the consequences of this (increased action of heart, &c.), one has walked 22 miles in the time ordinarily taken to walk 13.

A VIEW OF ETNA

To put it in another way: 390 foot-tons is a hard day's work, as it is found that something over 300 foot-tons is the average day's work of strong labourers. One therefore does a hard day's work in $3\frac{1}{4}$ hours, and this after an ordinary day's work, *plus* a fatiguing ride of some four hours on a mule, over lava currents and cinders, in the middle of the night and without any chance of sleep.

Taking everything into consideration, it is difficult to believe that the fatigue is, as it is often stated, out of all proportion to the work done; we must not only consider the amount of work, but *the time in which it is done*, and this is what I have especially wished to point out, as one can easily understand that the fatigue must increase very fast as the time in which the work is done decreases.

At the summit of Etna (the accompanying woodcut, from a rough sketch taken when a good deal of the snow had melted, can give but a feeble idea of the exquisite effect produced by the dazzling whiteness of the snow against the perfectly clear blue Sicilian sky) the range of temperature within a few feet of vertical distance is very remarkable. Just after sunrise I found that the temperature of the air at the height of four feet or so above the ground was -2° C.; on the ashes where the snow had melted it was $+9^{\circ}$ C.; just under the surface it was 20° C., and a few inches under it was higher than 36° C. (my minimum thermometer, the only one I had left, not allowing me to register a higher temperature than this).

This high temperature of the ashes only occurs where they are mixed with sulphur, which is continually undergoing oxidation; the other parts of the cone and crater are in the winter covered with snow, and it is very strange to see snow a foot deep or more, quite close to ashes that really feel uncomfortably hot.

Those who wish to "get up" the history of Mount Etna and its structure, should refer to Sir Charles Lyell's "Principles of Geology," tenth edition, vol. ii.; or for a much more detailed account of the eruptions, its present and past conditions, &c., to "La Vulcanologia dell' Etna," by Carlo Gemmellaro, published at Catania in 1858.

W. H. CORFIELD

NOTES

As will be seen from another column, the Eclipse Expedition is now fully organised, and all the parties will be on their way before our next number appears. The Organising Committee, who have done about three months' work in a fortnight, deserve all praise for their untiring efforts, and we may hope that they will be adequately rewarded by the results obtained. We may mention that on the representation of the Organising Committee, the Government have communicated with the French and German Governments with a view of securing the services of M. Janssen, who, if he can be got out of Paris, will accompany Mr. Lockyer to Sicily.

It is stated that Prof. H. J. S. Smith, F.R.S., has been appointed to succeed the late Dr. W. A. Miller as a member of the Royal Commission on Scientific Instruction and the Advancement of Science.

The annual election of the Council and officers of the Royal Society took place yesterday, when the following gentlemen were elected, viz. :—President: Gen. E. Sabine, K.C.B. Treasurer: William Spottiswoode, M.A. Secretaries: William Sharpey, M.D.; G. G. Stokes, M.A. Foreign Secretery: Professor W. H. Miller, M.A. Other Members of the Council: George Burrows, M.D.; Heinrich Debus, Ph.D.; P. M. Duncan, M.B.; Sir P. de M. Grey Egerton, Bart.; Prof. G. C. Foster, B.A.; Francis Galton; J. P. Gassiot; J. D. Hooker, C.B, M.D.; William Huggins; Prof. G. M. Humphry, M.D.; J. Gwyn Jeffreys; Sir J. Lubbock, Bart.; C. W. Siemens; Prof. A. J. S. Smith, M.A.; Prof. John Tyndall, LL.D.; and Prof. A. W. Williamson, M.D.

It is with very great regret that we have to announce the disablement of two of our most prominent scientific men. Sir R. I. Murchison has been stricken with an attack of paralysis, and Professor Balfour Stewart was among the sufferers by the collision on the London and North-Western Railway on Saturday evening last. In the latter case, though the injuries are severe, one thigh broken, and a great shock to the nervous system, we may hope that Professor Stewart will shortly be restored to his friends and to science. At the moment of going to press, we hear that Sir R. Murchison's state is considered somewhat improved, and that Sir W. Ferguson reports Prof. Stewart to be going on satisfactorily.

The Anniversary Session of the St. Andrews Medical Graduates Association will be held at the Freemasons' Tavern, Great Queen Street, on Friday and Saturday, December 2nd and 3rd. On Friday, at 7.30 P.M., Dr. Whitmore will read a paper "On the results of Sanitary Legislation on the Health of the Metropolis and our present urgent Sanitary requirements." On Saturday, at 5 P.M., the President, Dr. Richardson, F.R.S., will deliver the Anniversary Address "For the Future of Physic."

At the first ordinary meeting for the session of the Society of Arts, held on the 16th ult., the following silver medals were awarded:—To Mr. Thomas Dickins for his paper "On Silk Supply;" to Mr. James Collins for his paper "On Indiarubber, its History, Commerce, and Supply;" and to Mr. William Bridge Adams for his paper "On Tramways for Streets and Roads and their sequences.;" and the Prince Consort's Prize of twenty-five guineas to Mr. Edward Turner Sim, who, at the Society's examination, had obtained during the last four years the largest number of first-class certificates.

Counts H. Wilcjek and G. Wurmbrand have been engaged, at the instance of the Viennese Anthropological Society, in an examination of the Austrian lakes, and have found remains of pile-dwellings in the Attersee. One of them belongs to the Stone period.

At the remote city of Indianapolis an Academy of Sciences has just been formed under the presidency of Professor E. T. Cox. The exclusive object of the association is the cultivation and imparting of knowledge of the natural and physical sciences. Though the number of members at present does not appear to be large, it will, no doubt, like most other things in the Far West, increase rapidly. We wish all success and a prosperous future to this the youngest society for the advancement of natural history.

The recently published volume of Bentham's "Flora Australiensis" (vol. v.) includes the natural orders from Myoporineæ to Proteaceæ.

Messrs. Macmillan will shortly publish, as one of their series of school class-books, Lessons in Elementary Physics, by Prof. Balfour Stewart.

We have just received the first part of the second edition of Schellen's Spectral-analyse. The preface states that it has been carefully revised, and considerable additions made, in accordance with the progress of science since the publication of the first edition, especially in the application of spectrum-analysis to the sun. It is copiously and beautifully illustrated.

The third section of "Husemann's Pflanzenstoffe in chemischer, physiologischer, pharmakologischer, und toxikologischer Hinsicht," does not, as was expected, complete the work. It is occupied with vegetable acids and neutral substances.

Mr. Matthew Williams, jun., has reprinted, from "Essays of the Birmingham Speculative Club," a paper on "The Relation of the Universities to Practical Life." The writer's aim is to assert the claims of experimental science to a higher place in the scheme of English University education. It is monstrous that such a plea should still be necessary. While it remains so, however, we welcome all who, like Mr. Williams, can break a lance in the cause of true progress in such a manner as to appeal even to the most "practical" sympathies. Why should not others in the great centres of English industry take up the subject? Agitation works wonders in the political world; who knows what it might not in time effect for science?

On the 7th of August the most severe shock of earthquake since April 1868, has been felt in the Hawaian Archipelago. The time was $4^h\ 10^m$ A.M., and the shock was felt generally in Maui, Molokai, and Hawaii, but not so much in Honolulu. The damage done was not so great, but it was considered remarkable that the shock lasted ten seconds—a long period for a single shock. The cause of its diminished violence is attributed to its being vibratory and extremely regular. In Molokai the earthquake was accompanied by a tremendous roar, and appeared to have a circular motion, so that no precise direction could be noticed. It is stated that the fissures on the Kau side of Mauna-loa are constantly steaming, and that smoke is issuing from the crater of Makeaweoweo in great volume.

H.M.S. *Zealous*, bearing the broad pennant of Admiral Farquhar, having visited St. Charles, one of the Galapagos Islands, has found sufficient objects of interest to induce the Admiral to make another trip there in October, to examine the natural history of the place.

On Thursday, the 29th September, two violent shocks of earthquake occurred at Lima, in Peru, about 10 P.M., causing much alarm.

A passenger reports to the *Rangoon Times* a waterspout seen on the Irawaddy River on the 31st of August in the Chwaygeen Creek. He saw a dense mass of clouds, and then a whitish cloud, which resolved itself into a large waterspout. It soon partially dispersed, but formed again, and remained about ten minutes, sometimes straight, at others curved. The convex side was to the wind. The spout appeared to be rapidly skimming the surface of the river, the water rising like spray round it, and having a spiral appearance along the shaft. The phenomenon was not accompanied by noise or thunder and lightning.

WE have received the reports of the Mining Surveyors and Registrars, Victoria, for the quarter ending 30th June, 1870. In some instances steady improvement is reported, but there are also numerous complaints of a considerable falling off in the yield of gold. The total number of miners employed in the colony during the quarter was 60,267. Of these, 28,227 Europeans and 15,478 Chinese were employed as alluvial miners, 16,500 Europeans and 62 Chinese as quartz miners. In alluvial mining 399 steam-engines of 9,657 aggregate horse-power were used in winding, pumping, &c. ; and in quartz mining 701 steam-engines, of 13,283 aggregate horse-power. The approximate value of the mining plant was 2,144,727*l*. 1,021½ square miles of auriferous ground were actually worked upon, and 2,782 distinct quartz reefs were actually proved to be auriferous. The Mining Surveyors and Registrars are unable to obtain perfectly full information respecting the quantities of quartz, &c., crushed or operated upon ; but the following is a summary of the leading facts which they detail :—The total quantity of quartz crushed was 223,285 tons 14 cwt. 36,909 tons 7 cwt. of quartz tailings, cement, and mullock were crushed, and 868 tons 15 cwt. 2 qrs. of pyrites and blanketings were operated on. The average yield of gold per ton from quartz was 9 dwt. 11·38 gr. ; from quartz tailings, cement, and mullock, 3 dwt. 0.39 gr. ; from pyrites and blanketings, 2 oz. 6 dwt. 13·37 gr. The total yield of gold from quartz was 105,775 oz. 18 dwt. 19 gr. ; from quartz tailings, cement, and mullock, 5,566 oz. 9 dwt. 1 gr. ; from pyrites and blanketings, 2,022 oz. 7 dwt. 18 gr. Appended to the reports is a careful geological map of portion of the Durham Lead, with a paper on the subject by Mr. Reginald A. F. Murray. Mr. Murray describes the physical and geological aspects of the district traversed by the Durham Lead, discusses the question whether it is or is not the main outlet of the Golden Point Gutter, and gives a brief account of the claims lying within the portion of the lead immediately under consideration.

IF we may judge from its last annual report, the proceedings of the Bombay Geographical Society are not much enlivened by the efforts of its members. During the entire session not a single member had favoured the Society with any original communication. For some time the Society has been considering the propriety of getting compiled an Anglo-Vernacular Index of Indian Geographical names. The scheme would supply a want that has long been felt, but it does not appear to have received much encouragement from the authorities, to whom an appeal for aid in the matter was addressed. The "Transactions" of the Society for the year ending December 1869, are made up of some interesting notes on Annesley Bay, by Mr. Edwin Dawes, and a brief paper by Mr. J. U. Yajnik, on the Hot Springs of Lasúndrá, in the Kairá Zillá.

ANOTHER proof of the desirability of earnest experiments in the widespread cultivation of economic plants is shown in the success which has attended the introduction of tobacco in some of our own colonies. Samples of Latakia tobacco grown in Jamaica have been submitted for approval in London, and reported upon favourably ; and from India we hear that the seeds of the best varieties are being distributed in the districts most suited to the cultivation of the plants. From Natal, a sample has just been received, and submitted to an eminent firm of tobacco brokers in the City, who report that it is a very near approach to what colonial tobacco should be. It is of good substance, and of a fair light brown colour, and would, if carefully packed, in all probability fetch a price of from 5*d*. to 5½*d*. per lb. in bond, and would meet with a ready sale to a rather large extent in the London market. The principal requirements of a good tobacco are brightness of colour and dryness of condition, the latter being most essential in consequence of the high rate of duty. Green and imperfect leaves should be excluded, and great care should be taken in packing, so as not to injure or crush the leaves. An important point in the curing of tobacco is to ensure its burning well, and holding fire. A good opportunity presents itself at the present time for the introduction into our markets of colonial tobacco, owing to the general scarcity both of the continental supplies and of other kinds usually substituted for the American product in the manufacture of cut tobaccos.

AS an instance of the rapidity with which introduced plants spread, when soil and climate are congenial to their habits, we may point to the *Euphorbia prostrata*, Ait, a little annual weed in Jamaica and Trinidad, which became introduced by chance about ten years since into a garden in Madeira, situated some 400 feet above the sea ; from this spot it has rapidly spread down the steep road to the town ; while up the other hills, separated by deep ravines from that down which it came, it has scarcely crawled at all, a downward course apparently being far easier for it than an upward one. It has, however, slowly crept up another hill at the rate of about ten feet a year. The seeds, which are described as ecarunculate, with sharply tetragonal palæ, transversely keeled, are well adapted for sticking to the clothes of travellers, and to be carried about, so that we might well expect the plant to crop up in all directions. Mr. Lowe says that it is now to be found everywhere in Funchal below 500 feet.

THE pods of the Ground Nut (*Arachis hypogæa*) are frequently to be seen in the windows of small shops in the poor neighbourhoods of our large towns, where they are chiefly purchased by children, and are known to them as "monkey nuts." Their chief use, however, is for the expression from the seeds of a light coloured bland oil, said to be extensively used for mixing with olive oil ; and we have even heard of the seeds being parched and used as a substitute for coffee, but we now read that in America they are used for making chocolate (so called) ; for this purpose they are beaten up in a mortar and the mass compressed into cakes, and it is said to form a most agreeable chocolate without a particle of true cocoa. More than this, the Americans prepare the seeds as a dessert sweetmeat by parching them and beating them up with sugar.

THE disasters of a ship have made the Peruvians acquainted with the situation of a new guano island in the South seas. This is called "Baker's Island," in 12° N. lat. and 176° E. long. It has some smaller islands near, and is surrounded by coral reefs, on which thirty wrecks have been counted. The island has been taken possession of by a North American company, and is peopled by three Americans, of whom one is the governor, and about a hundred Kanakas. The cargo of the English barque *Borneo*, bound to London, consisted of a yellowish earth, which the Peruvians say has no smell of ammonia, but may sell at a profit to mix with Peruvian guano.

THE *Boston Journal of Chemistry* says that large factories have been established in New Orleans, Buffalo, and Brooklyn, or making grape sugar from corn. The latter is steeped in weak soda lye, for the purpose of softening the husk and gluten ; and is then ground wet, and run through revolving sieves to separate impurities. It is afterwards made to flow through ways or troughs, in which the starch gradually settles as a white powder. The wash water is run into a large cistern, and allowed to ferment and produce a weak vinegar. The starch from the troughs is put wet into the mash-tub, and treated with water containing one per cent. of sulphuric acid, for eight hours. The acid is neutralised with chalk or carbonate of lime, and the liquid evaporated to get rid of the gypsum, and afterwards further evaporated in vacuum pans, and run into barrels ready for crystallisation.

MATERIAL changes are officially reported from the Bay of Talcahuano, in Chile, which was surveyed by Captain Fitzroy. The commander of the Chilean war steamer *Ancud* now reports that the water throughout the entire extent of the bay has increased from two to two-and-a-half fathoms. This represents great geological change. The rock Fraile, in the Gulf of Arauco, represented on Fitzroy's chart as a sunken rock, is now, however, a small island united to the mainland, opposite to the western bank of the river Tubul, and has rather the shape of a quadrangular pyramid.

THE *Times of India* states that the coal-beds discovered in Bellary are excellent in quality and abundant in quantity. Great anxiety is felt for Dr. Oldham, who said he would eat all the coal found in the Madras Presidency, for the doctor is a man of honour.

FROM a considerable number of observations on the temperatures of the two sides of the body, Mr. Blake draws the following conclusions, which are recorded in the *Medical Times and Gazette* of October 8, 1870:—1. That the temperature of the sides of the trunk under usual circumstances, *i.e.* in health and at rest in a temperate climate, is equal. 2. That under certain conditions the temperature of the left side of the trunk may exceed that of the right. 3. That that excess during exertion in a cool atmosphere averages half a degree F. 4. That that excess reaches its maximum of about one degree F. during exertion under a powerful sun.

THE GEOGRAPHICAL DISTRIBUTION OF DEER*

IN his excellent "Geographische Mittheilungen," Dr. Petermann has lately given us several *zoo-geographical* articles, as we may call them—such as those of Dr. Finsch on the distribution of Parrots, and of Freiherr von Heuglin on the Bird-fauna of North-eastern Africa. Both of these memoirs are the products of the highest authorities on the subjects to which they respectively relate, and deserve our warmest commendation. We cannot, however, say so much as to the merit of the paper upon the Geographical Distribution of Deer, which appears in a recent number of Dr. Petermann's journal. The authors of this memoir, which, if properly treated, is on a subject of very great interest, have, we fear, commenced to indulge in "generals" before having sufficiently got up their "particulars." In the first part of their essay they point out the present distribution of the different genera and species of *Cervidæ* over the world's surface, and endeavour to show how they have descended from a common ancestral form. This form they imagine must have been the *Moschidæ*, upon the ground that in order to obtain a deer with horns we must pre-suppose the existence of a deer without horns, and the *Moschidæ* answer this definition. Unfortunately, however, the authors have not yet discovered that their so-called group *Moschidæ* is composed of two forms of animal life that have very little to do with one another. It has been shown most conclusively by the researches of M. Alphonse Milne-Edwards† in Paris, and Prof. Flower in our own country,‡ that the *Chevrotains* (*Tragulus* and *Hyomoschus*), one of the constituents of the *Moschidæ* of MM. Jaeger and Bessels, constitute a family *per se*, quite distinct from the rest of the ruminants, and connecting them with the pigs, and consequently quite distinct from the musk-deer (*Moschus*). In the same way our authors base certain arguments upon the fact of all the typical deer being spotted in the immature state. But, as Dr. Jaeger at least—having been, if we are not misinformed, custos of a zoological garden—ought to know, this is not quite the case, all the *Rusine* deer having their young spotless. Again, arguments are founded upon *Cervus pudu* of Chili living in the Cordilleras, and the other allied species with simple unbranched horns in the plains of South America. But exactly the contrary is the case. *Cervus pudu* is from the low maritime coast of Chili, and one, if not more, of the so-called "*Subulones*" (*C. rufius*) lives high in the Andes of Venezuela and New Granada. From these and other similar instances of erroneous statements which it would be easy to point out, it is, in fact, quite obvious that the authors of this essay have no very special acquaintance with the group upon the distribution of which they treat. We leave it to naturalists to decide whether, under these circumstances, the results arrived at are worthy of much attention. Their theory seems to be that the deer-family reached the New World by an Arctic continent which formerly connected northern Europe with eastern America, and which Dr. Jaeger, in a former paper, has proposed to call "*Arctis*." There are, however, if we are not mistaken, equally good grounds for believing that the numerous, undoubtedly Old-world forms in North America reached it by immigration from North-western Asia.

HENDERSON'S PATENT STEEL PROCESS

TWO articles written by Mr. W. Mattieu Williams, called "Papers on Iron and Steel—A Costly and Vexatious Fallacy," were published a short time since in NATURE. These papers are considered in this country to be the clearest and ablest that have ever appeared on this subject, setting forth the reason why all efforts heretofore made to produce steel from English cast-iron by partial decarbonisation have failed; that all manipulations have been directed to removing as much as possible the impurities contained in pig iron by oxidation. He was not aware that new agents have been used, combined with oxygen, and that patents had been granted therefor in England, Nos. 318, 1,051, A.D. 1870 (which were not then published) for combining fluorine with oxygen, and fluorine combined with titanic acid, or with titanium and oxygen.

The new patent process for the production of steel by the partial decarbonisation of cast-iron consists in the combined use of fluorspar or other fluorides and titanic acid, applied to cast-iron at the melting temperatures, preferably in reverberatory furnaces. Fluorine is given off from the fluorspar, and is a more powerful agent for the removal of silicon than oxygen, and removes it almost entirely from the cast-iron before the reactions with the carbon begin; the phosphorus and sulphur are next acted upon and removed in the order they are named by means of the combined action of fluorine and titanic acid or fluorine, titanium, and oxygen, and lastly the carbon is removed. The fluorine is derived from fluorspar combined with iron ores containing titanic acid in such wise as ensures simultaneous action of the fluorine, titanium, and oxygen upon the cast-iron; and by reason of the affinities of these substances for silicon, phosphorus, sulphur, manganese, arsenic and carbon, these substances are taken from the iron in the form of vapour and slag, leaving the purified metal in the condition to be hammered or rolled as merchantable steel.

English pig-iron may be made direct into steel by the new process; and with the large class of irons smelted from hæmatites and specular ores with good fuel, *pure* steel may be made, that will be entirely desiliconised, dephosphorised, and desulphurised, and contain but the required amount of carbon to form steel of any particular degree of hardness, by arresting the decarbonisation of the metal whilst undergoing conversion.

Experiments were made in May last on a large scale at Messrs. Park, Brothers and Co.'s Steel Works, in Pittsburg, in boiling puddling furnaces fettled with such oxides, but without puddling or labour of stirring the iron during conversion; the only labour was that of "balling" and removing it from the furnace after the conversion was completed. The mode of application in the above-named establishment was 125lb. of titaniferous iron ore (similar to the Norwegian) and 50lb. of fluorspar, both in a powdered state, and then charging them evenly over the sole of the furnace. 475lb. of No. 3 charcoal pig-iron, similar in quality to English hæmatite of Barrow, was then charged upon them, and, when melted, was allowed to remain without stirring or puddling. As soon as the pig-iron melted, reactions began between the fluorspar and the titaniferous iron ore, and the silicon and phosphorus contained in the pig-iron. To ascertain exactly the conditions upon which the changes are made in the cast-iron whilst under treatment, samples were taken from the bath of liquid iron. The analysis of the first sample shows that the operation of the new process is entirely different from any other process, inasmuch as the silicon is entirely removed at the early stages of the process; and, with the silicon, phosphorus is also taken from the iron, and the carbon is changed from the graphitic to the combined form. Other samples were taken from the bath at intervals of ten minutes. The analysis of the first sample made it evident that most of the later ones were steel. This has since been confirmed by analysing a specimen taken thirty minutes later from the bath, and by the treatment of them as steel, it having been found that they possess the properties of steel, forging well, and tempering and hardening according to the various degrees of carbon contained in them. At the end of the operation, the charge became wrought-iron, by removal of *all* the carbon. This iron forges, welds, and is neither red-short nor cold-short.

The analyses of the first and fourth samples taken from the bath have been made by Mr. W. M. Habirshaw, analytical chemist, of 36, New Street, New York, and are annexed. Also, analyses of Messrs. Sanderson's and Krupp's cast-steel, and Hoop L Dannemura-Swedish bar iron are annexed for comparison, taken from Dr. Percy's "Iron Metallurgy."

First Sample. Refined Cast-iron, taken 40 minutes after fusion.		Fourth Sample. Steel, taken 30 minutes later.	
Carbon, combined	2·7144	Carbon, combined	0·2172
do graphite	traces	do graphite	none
Slags (silicates)	none	Slags (silicates)	none
Silicon	0·0046	Silicon	none
Phosphorus	0·0349	Phosphorus	none
Sulphur	0·1073	Sulphur	very minute trace
Titanium	trace	Titanium	none
Fluorine	none	Fluorine	none

The presence of sulphur in the refined cast-iron is mostly due to sulphurets mixed with the fluorspar, which was used in the condition in which it was taken from the mine, there being no convenience at hand for dressing it.

Later experiments with other kinds of pig-iron, with impure or fluorspar not dressed, show that at the stage of the process where it becomes refined cast-iron, the increase of sulphur from this cause amounts to 0·1051 per cent.; which with "dressed" or pure fluorspar, would be 0·0022 per cent. of sulphur for the refined cast-iron of the foregoing analysis, instead of 0·1073 per cent.

It will be evident to the practical metallurgist that the refined cast-iron, when treated with *pure* fluorspar, becomes steel of superior quality when decarbonised below 1·90 per cent of carbon.

Hoop L Bar-iron.		Sanderson's Cast-steel.		Krupp's Cast-steel.	
Carbon	0·087	Carbon	not deter.	Carbon	1·18
Silicon	0·115	Silicon	0·24	Silicon	0·33
Phosphorus	0·034	Phosphorus	0·02	Phosphorus	0·02
Sulphur	0·220	Sulphur	0·05	Sulphur	none
Manganese	none	Manganese	0·03	Manganese	trace
Arsenic	trace	Cobalt, nickel	none	Cobalt, nickel	0·12
Cobalt, nickel	none	Copper	none	Copper	0·30
Copper	none	Aluminium	0·12	Aluminium	none
Aluminium	none				

From the foregoing analysis it will be seen that the *refined cast-iron* of the patent process contains but $\frac{1}{25}$ part of the silicon, less than one half the sulphur, and about the same amount of phosphorus, as compared with Hoop L bar-iron. This is the most celebrated wrought-iron made in the world, and is used exclusively for making steel, and sells at 24*l.* per ton at Sheffield.

The analysis of the steel of the patent process shows, as compared with Sanderson's and Krupp's, that while the latter are alloyed with carbon, silicon, sulphur, phosphorus, &c., the *steel* of the new process is practically *pure* iron and carbon.

In the articles before referred to, written by Mr. Williams (and from his intimate practical and scientific knowledge no better authority can be had), he says:—"To make *perfect* steel they take out *all* these latter, and leave nothing but pure iron and carbon. Absolute perfection is not, of course, practically attainable in steel making, but it is approximated in the same degree as the purification of iron from everything except carbon is effected."

Persons wishing to satisfy themselves of the value of the process, by a test, should use the ordinary boiling puddling furnace, fettled with the purest red hæmatite or specular ores, containing the least silica, ground and applied wet, with the ordinary "bottom" made in the usual way: and when perfect steel is required, that contains neither silicon, phosphorus, nor sulphur, good pig-iron should be taken, such as Nos. 1 and 2 Barrow, or West Cumberland hæmatite; and treated with pure fluorspar, and titaniferous iron ore from the Bay of St. Paul, in Canada, containing over 43 per cent. of titanic acid, or from Norway, containing over 40 per cent. of titanic acid; using 48lb. of fluorspar to 118lb. of the ore. They should be ground to fine powder, and mixed, and used dry, and charged evenly over the sole or bottom of the furnace; and 475lb. of pig-iron should be charged upon them, and the furnace closed tight so as to exclude all air, for about 70 minutes. The fire should be kept to the highest temperature. After the metal has been in the furnace this period, samples should be taken from the bath at intervals of five minutes. It will be found that a little experience will soon determine the proper time to stop the process.

It is best *not* to allow the workman attending the furnace to stir or puddle the metal during the conversion, as the fluorspar and titaniferous ore become viscid by the heat of the furnace by the time the pig-iron melts, and, if left alone, will remain on the bottom of the furnace until decomposed by the reactions of the process, when they pass through the iron as vapour and slag, and purify it more effectively than can be done by stirring or puddling; and the slag serves to protect the surface of the metal from the effects of the sulphur in the fuel. The only labour that should be *allowed* is that of removing the steel from the furnace at the required stage of conversion.

The time in conversion of the steel, from the charging of the pig-iron, is one hour and 30 to 40 minutes; this time may be shortened 30 to 40 minutes, by previously refining the cast-iron of all its silicon and most of its phosphorus, by a shorter and more economical process (Patent, No. 1,051) with hæmatites and specular ores with fluorspar, which will become the subject of a future article.

JAMES HENDERSON

New York

SOCIETIES AND ACADEMIES

LONDON

Geological Society, November 9.—Mr. Joseph Prestwich, F.R.S., President, in the chair. Lieutenant Reginald Clare Hart, R.E., Brompton Barracks, Chatham; Lieutenant James Frederick Lewis, R.E., Brompton Barracks, Chatham; and Mr. M. F. Maury, jun., 1300 Main Street, Richmond, Virginia, U.S., were elected Fellows of the Society.—(1.) "On the Carboniferous Flora of Bear Island (lat. 74° 30′ N.)," by Professor Oswald Heer, F.M.G.S. The author described the sequence of the strata supposed to belong to the Carboniferous and Devonian series in Bear Island, and indicated that the plant-bearing beds occurred immediately below those which, from their fossil contents, were to be referred to the mountain limestone. He enumerated eighteen species of plants, and stated that these indicated a close approximation of the flora to those of Tallowbridge and Kiltorkan in Ireland, the greywacke of the Vosges and the southern Black Forest, and the *Verneuilii*-shales of Aix and St. John's, New Brunswick. These concordant floras he considered to mark a peculiar set of beds, which he proposed to denominate the "Ursa-stage." The author remarked that the flora of Bear Island has nothing to do with any Devonian flora, and that consequently it and the other floras, which he regards as contemporaneous, must be referred to the Lower Carboniferous. Hence he argued that the line of separation between the Carboniferous and Devonian formations must be drawn below the yellow sandstones. The presence of fishes of Old Red Sandstone type in the overlying slates he regarded as furnishing no argument to invalidate this conclusion. The sandstones of Parry Island and Melville Island are also regarded by the author as belonging to the "Ursa-stage," which, by these additions, presents us with a flora of seventy-seven species of plants. The author remarked upon the singularity of plants of the same species having lived in regions so widely separated as to give them a range of $26\frac{1}{2}°$ of latitude, and indicated the relations of such a luxuriant and abundant vegetation in high northern latitudes to necessary changes in climate and in the distribution of land and water.—Sir Charles Lyell remarked that the Yellow Sandstones of Dura Den in Fife, and of the county of Cork in Ireland, contain *Glyptolepis* and *Asterolepis*, genera of fish exclusively Devonian, or belonging to the middle parts of the Old Red Sandstone—also the genus *Coccosteus*, which is abundantly represented in the Middle Old Red Sandstone, and sparingly, or only by one species, in the Carboniferous formation. The evidence derived from these fishes inclined him to the belief that the Yellow Sandstone, whether in Ireland or Fife, should be referred to the Upper Devonian, and not to the Lower Carboniferous, as Sir Richard Griffiths contended, and as Heer now thinks. As to the argument founded on the plants, he considered it an important and truly wonderful announcement, that many well-known Carboniferous species are common to Bear Island (in lat. 74° 30′ N.), in the Arctic regions and to Ireland and other parts of Europe (26° of latitude farther south). But fossil plants are supposed to have a wider range in space and time than fossil fish; and we know that the cryptogamic flora of the ancient coal is remarkable for the wide horizontal spread of the same species, extending from North America to Europe, so that we need not be surprised if many species should extend vertically from the Devonian into the Carboniferous strata. Mr. Carruthers remarked on the bearing of the paper on the Kiltorkan beds, and considered that Dr. Heer had completely established the correlation of the deposits. He differed, however, as to the numerical proportions of the species. He could not recognise *Cyclostigma* as a genus, but considered it founded on insufficient grounds, in which view Prof. Haughton now agreed. It was, in fact, founded on fragments of the bark of *Lepidodendron Griffithsii*, Brongniart, to which species the *Lepidodendron* indicated by Prof. Heer as *L. veltheimianum* really belonged. Other detached portions of this same plant had been described by various authors under no less than seven different specific names, and referred to nearly an equal number of distinct genera, and Prof. Heer had reckoned these as species in his comparison of the Bear Island and Irish floras. Prof. Heer had been led, chiefly by the erroneous determination of the Kiltorkan *Lepidodendron* by the Irish palæontologists, to refer these beds to the Carboniferous rather than to the Devonian formation, the Kiltorkan fossil having been established as a very distinct species by Brongniart and Schimper. Mr. Carruthers considered that both the Irish and Bear Island deposits belonged to the Devonian. Mr. Boyd Dawkins pointed out that the proximity of land was exhibited by the presence of terrestrial plants in the deposits, and believed that this might have much to do with the difference in the proportion in the beds. As the marine fauna decayed more rapidly than the terrestrial, it was preferable for classificatory purposes. He mentioned forms of vegetable life which had been recently discovered in America in beds of Cretaceous age. He did not believe that corals could have existed in those high latitudes under anything approaching to the present condition. Prof. Nordenskjöld had failed to discover any traces of glacial action in these beds; and the question arose whether there had been any change in the position of the Pole or in the radiated heat of the sun.—(2.) "On the Evidence afforded by the Detrital beds without and within the North-eastern part of the Valley of the Weald as to the mode and date of the Denudation of that Valley." By Mr. S. V. Wood, jun., F.G.S. The author commenced by discussing the various hypotheses that have been proposed to explain the denudation of the Weald Valley. In his opinion the upheaval of the district took place in Post-glacial times, and subsequently to the deposition of the gravels of the Thames Valley, of East Essex, and of the Canterbury heights; and the denudation was effected chiefly by tidal erosion during gradual upheaval in an inlet of the sea, aided by the action of fresh water flowing into this inlet from the north by streams draining the land which now constitutes the counties of Middlesex and Essex. The chief evidence in favour of his views is as follows:—1. The absence from the glacial beds of Essex of any débris representing a considerable denudation of the Weald during the glacial period, and the probability that the Wealden area was beneath the sea during the deposition of the Boulder Clay. 2. The comparative absence of Lower Cretaceous or Hastings-sand materials from the Post-glacial gravel-sheets outside the north of the Weald. 3. The impossibility of reconciling the presence of Tertiary pebbles in certain Weald-gravels with an origin by means of streams flowing in the direction of the present rivers. 4. The antagonism between the character of the major valley of the Weald and that of any excavation producible by the agency of rivers. 5. The persistence of the old coast contour with the river-drainage entering it from the north. 6. The existence of a cause, in the shape of an isthmus at Dover, sufficient to induce a strong tidal scour. Mr. Godwin-Austen thought that the author had done his theory injustice in presenting only a portion of the Wealden area for consideration. He remarked that phenomena similar to those of the Weald were to be found in various parts of Western Europe. He was glad to find that Mr. Searles Wood did not regard the escarpment as representing marine cliffs; but he did not attach sufficient weight to the absence of any material of marine origin at their base, so that there was no evidence of the presence of the sea within the Wealden area. He differed wholly from the author as to the age of the gravels, for beneath the gravels were silty beds containing elephant remains. These gravels he was inclined to refer to a glacial period, as they contain blocks such as could only have been transported by the agency of ice. The elephants found in the valley of the Wey are of the species (*E. primigenius*) which also occurs in the Selsea beds; and he believed both to be of glacial age. As to the theory of the denudation of the Weald, he professed himself a convert to the views of Messrs. Foster and Topley, and cited what was now going on in Heligoland in illustration of atmospheric denudation.—Mr. Whitaker observed that the present absence of gravels along parts of the valley of the Thames affords no proof of their not having formerly existed. He pointed out the soft and friable nature of most of the rocks of the Wealden, which would account for their absence in the gravels. The only really hard rock was the Chert of the Lower Greensand, which was abundant in the gravels of West Kent. Angular flints occurred at the base of the chalk escarpment wherever it had been carried back by denudation. The major valley of the Weald had been spoken of, but he denied that any such valley existed; it was merely a series of numerous small valleys. He could not conceive the rivers flowing against the dip of the strata, as supposed by Mr. Wood. He did not agree in the view of the denudation of the Weald being such an enormous affair, but thought that it might be due to comparatively small causes.—The President pointed out that beyond Southend there was a section precisely similar to that of Grays. It was a mistake to suppose pebbles from the Wealden area did not occur in the Thames gravels.

He thought that much of the denudation of the Wealden area might have taken place before the glacial period. The presence of Tertiary pebbles in the Wealden area might readily be accounted for by their presence at the edge of the escarpment. Mr. Searles V. Wood, jun., in reply, justified himself for having limited his observations to the northern part of the Weald, as it was there only that it could be brought into juxtaposition with the glacial beds. He maintained that, under certain circumstances, no beaches or marine beds were formed at the base of sea-cliffs. He pointed out that in Post-glacial gravels large blocks of rock were frequently found, and protested against limiting all ice-transport to the glacial period. He could not recognise the Selsea beds, with 150 living species, some of southern character, and none extinct, as glacial. He did not acknowledge the alleged softness of the Wealden rocks.—The Earl of Enniskillen sent for exhibition a fragment of Lias Limestone from Lyme Regis perforated by *Pholades*.

Entomological Society, November 21.—Mr. Alfred R. Wallace, F.Z.S., &c., President, in the chair. Exhibitions of *Lepidoptera* were made by Mr. Bond; of *Coleoptera* by Mr. Albert Müller and Prof. Westwood; and Mr. F. Smith exhibited *Phora florea*, a Dipterous parasite in the nest of the wasp. The following paper was read:—"Descriptions of some new diurnal *Lepidoptera*, chiefly Hesperiidæ," by Mr. A. G. Butler.

Ethnological Society, November 22.—Prof. Huxley, President, in the chair. Mr. George Macleay was announced as a new member. Mr. Edgar Layard made some remarks upon a collection of stone implements which he has recently brought from the Cape of Good Hope. Some polished celts from the Naga Hills, between Assam and Burmah, were exhibited, and Lieut. Barrow's notes upon them were read.—A paper was then communicated by Dr. Bleek "On the Concord, the Origin of Pronouns, and the Formation of Genders or Classes of Nouns." The author believes that the classes or genders in the sex-denoting languages originally depended, not upon the meaning of the nouns, but upon their representative particles, which, in these languages, were primiarily at the end of the nouns. These genders were, from an originally large number, gradually reduced, until in the Aryan languages they were mainly two—one with the representative element, U, which is called the *masculine* class, and the other with the representative element, A T I, which is named the *feminine* class. The *neuter* appears to be a later development, into which, however, an original common plural gender, with the termination, A N I, may have been incorporated. To these endings the case-terminations were affixed, and through pressure of the latter the original marks of gender have frequently been obscured. The concord was at first due to the presence of these representative elements of the nouns in their pronominal character. Mr. Hyde Clarke, in eulogising this paper, said that he had by independent investigation arrived at some of the results detailed by the author. The speaker insisted upon the necessity of extending our philological studies beyond the Indo-European languages.

Manchester

Literary and Philosophical Society, November 15.—Mr. E. W. Binney, president, in the chair. "On the Temperature Equilibrium of an Enclosure containing a Body in Visible Motion," by Prof. Balfour Stewart, LL.D., F.R.S. It has been established that in an enclosure containing bodies which are all at the same temperature, and at rest, the same amount of heat enters any surface forming part of the walls of the enclosure as leaves it in the same time, so that the body, of which this is the surface, neither gains nor loses heat. It is also known that if we take, not the outer surface of such a body, but any plane passing through its substance, say for instance one parallel to its outer surface, then, as much heat passes across this plane going into the body, as passes across it going out of the body in the opposite direction; and further, this equilibrium of heat is known to hold separately for every one of the individual rays of which the whole heterogeneous radiation is composed. The effect of the motion of a body in altering the wave-length of the radiated light is also well known. In consequence of this, if a cosmical mass, such as a star or nebula, should be formed of incandescent hydrogen, and be at the same time rapidly approaching the earth, the light which strikes the earth will not be the double line D, but a line more refrangible than it, and therefore this light will be able to pass through a mass of ignited sodium vapour at the earth's surface without suffering absorption, while, however, the light emanating from the sodium vapour will still be the double line D. In such a case, even if the star and the terrestrial sodium vapour should both be of the same temperature, yet the light radiated by the latter will not be the same in quality as that absorbed. This instance would appear to show that the equilibrium which holds in an enclosure of uniform temperature when all the substances are at rest does not hold when some of these are in visible motion, and that if in that enclosure there be a body moving towards or from the surface of the enclosure, the heat which enters the surface from the moving body will not be the same as that which the surface gives out. Suppose for instance that the walls of the enclosure are made of glass, and that the temperature of the whole enclosure including that of the moving body is 0° C., then, were the whole at rest, the heat which strikes the glass surface will all be absorbed at a very short distance below the surface, and in like manner the heat radiated by the glass will all emanate from a short distance below the surface. But let us now suppose, to take an extreme case, that the moving body is approaching one of the glass surfaces so rapidly that the heat which it emits has been so much increased in refrangibility as to enter the boundary of the visible spectrum. Then, while the heat radiated by the glass will still continue to proceed from a very short distance beneath the surface, the heat absorbed by the glass from the moving body will be able to penetrate to a very considerable depth beneath the surface of the glass. The outer layer of glass will thus lose, while the inner layer will gain heat. Now, it is possible to conceive an enclosure with a fixed diaphragm, and containing a revolving body, so arranged that the heat which leaves it in the direction of a certain part of the enclosing surface, shall always be given out by that part of the revolving body which is moving towards the surface; while, on the other hand, the heat given out by the revolving body to another surface, shall be given out when the revolving body is moving from that surface. There will thus be a want of temperature equilibrium among the various layers, those near the surface being somewhat different in temperature from those beneath. But when we have a temperature difference of this kind, have we not acquired the power of converting heat into work? It would thus appear at first sight that the mere presence of a moving body has given us the power of obtaining work from an enclosure all of whose particles were originally at the same temperature. This appears however to be opposed to the theory of the dissipation of energy, and in consequence we are induced to think there must be some error in the assumption. Now, does not the unwarranted part of the hypothesis consist in our supposing that the revolving system can continue to revolve without losing part of its visible motion? When two moving bodies approach or recede from each other, is it not possible that each loses a small part of its visible energy, while at the same time there is a surface disturbance produced in both? It might be said that, believing in a medium pervading all space, we were prepared for a stoppage of motion of this nature, and that there is therefore nothing gained by the supposition which has been made; but it might be replied that by looking at the problem in the above light, we appear to connect this stoppage of motion with other facts, besides being made aware of a source of surface disturbance when cosmical bodies approach or recede from each other.—Postscript added 19th November.—If we imagine a stoppage of the motion of cosmical bodies of the nature above described, then if the two approaching bodies be exactly equal and similar, either extremity of the medium between them will be similarly affected by the motion derived from the approaching bodies; but if these bodies are unequal, the two extremities of the medium will be dissimilarly affected.

Microscopical and Natural History Section, October 10.—Mr. Joseph Baxendell, President of the Section, in the chair. Mr. Joseph Sidebotham read the following paper:—"On the Variations of *Abraxas grossulariata*." The variations in animals and plants are of great interest, and each contribution to the store of facts accumulated relative to these variations, their causes and limits, is of value in determining the identity and limits of species, in whatever way we interpret the word *species*. *Abraxas grossulariata* is probably one of the most variable insects we possess in this country in colour and markings, and it would be quite pardonable in any one not well acquainted with it, were he to split it up into four or five species; but although it varies in colour and markings in such a great degree, all these varieties are joined together by gradual steps, and yet no step is found to join it to the next species on our list, *Abraxas ulmata*. The larvæ of this species will feed upon the leaves of most trees and shrubs, and are therefore easily experimented upon, as to whether the changes in food influence the colour or markings. So far as my own experiments, and I believe those of others are concerned, no difference whatever can be detected from the varieties of food, except in size. That long-continued changes of food through many generations might have a perceptible effect, is however more than probable. The type form of this moth is too well known to require description. I will therefore exhibit a drawer of specimens, having the type form in the centre, the various forms radiating from it in steps, in one line ending in white, another in black, another in which the white ground runs gradually into brown, and various other marked varieties. We may divide these into the following seven groups:—1. Variation. White, or the spots very few and distant: this leads up to the type form. 2. Spots joined together, forming curves and lines. 3. A variety of intermediate spots and patches. 4. The spots at the border becoming lines, and running towards the base of wings. 5. Spots confluent, forming solid black patches over nearly the whole of wings. 6. The spots having the type form, but the white ground tinged with a smoky brown or drab colour, sometimes suffusing the whole of the wings. 7. Spots of the type form, but the ground of wings bright yellow. From various experiments with many thousands of larvæ of this species, I have come to the conclusion that these variations are in a great measure hereditary, that one brood of eggs will produce moths of forms in a great measure identical, if the parents be of the ordinary type; if the eggs be the produce of moths of extreme colouring, varying much from the type, then, although the bulk of moths will be marked dark or light as the parents, there will be others of the ordinary type, and also some of the very opposite character of marking, precisely as in many florists' flowers the seeds from those varying most from the original form are known to produce the most marked and opposite varieties. These experiments can only produce approximate results, unless a great number of years could be devoted to them, and in this and many others of our most variable species, it is almost impossible to rear them in confinement beyond the second generation.

November 7.—Mr. Joseph Sidebotham exhibited a series of specimens of *Limobius dissimilis*, from Llandudno, on which the markings were very distinct and perfect; he discovered the species in considerable numbers beneath the flowers of *Geranium sanguineum*.—Mr. Spencer H. Bickham, jun., reported occurrence of *Myosurus minimus*, L., in plenty at Vale Royal, near Northwich, which species, he believed, had never previously been noticed in the neighbourhood. — Mr. Bickham then exhibited a series of specimens of *Polygonum minus*, Huds, collected at Mere and the surrounding district; he stated that he had searched for *P. mite*, Schrank, but without success, and believed with Mr. Hunt, that luxuriant specimens of *P. minus* had been mistaken for it: on the other hand he called attention to the fact that in 1859 Mr. John Hardy, to whom Mr. Bailey had previously alluded, distributed specimens of *P. mite* from Mere, through the Thirsk Exchange Club, and on this authority Mr. J. G. Baker, the Curator, remarked in the report, "new to the Mersey Province." It seems doubtful also whether *Alopecurus fulvus*, reported from the same locality, has not been erroneously recorded, peculiar states of *A. geniculatus* having been mistaken for it. As, however, it was found in considerable quantity at Oakmere in 1868, it appears probable that it may occur elsewhere in Cheshire.

Leeds

Field Naturalists' Club (Young Men's Christian Association), October 24.—The first meeting of the winter session took place this evening, Mr. Coates in the chair. In entomology, Mr. Liversedge exhibited specimens of *Latyrus ægeria*, *Argynnis selene*, *Anthrocharis cardamines*, and *Pamphila sylvanus*, all collected in this neighbourhood.—Mr. Turner exhibited a variety of insects taken near Selby, including *Cerura vinula*, *Triphæna fimbria*, *Argynnis paphia*, and *Saturnia carpini*. In oology, Mr. Coates brought the nest and egg of the ring ousel found at Ilkley.—Mr. Beevers and Mr. Taylor were the principal exhibitors in the conchological branch, Mr. Beevers exhibiting *Unio pictorum* from Went Vale, *Cyclostoma elegans*, Thorparch, and *Limnea palustris* var. *corvus*, Knaresbro.—Mr. Taylor exhibited *Limnea glabra*, *Helix virgata* var. *submaritima*, *Planorbis corneus* var. *albina*, and a small collection from Wisconsin, U.S.

November 7.—Mr. W. Coates in the chair. Mr. Taylor read a short paper describing a conchological visit to Boston Spa during the present month. Amongst the specimens taken were *Cyclostoma elegans*, *Helix lapicida*, *H. cantiana*, and *Pupa marginata*, specimens of which species, and a number of others, were exhibited.—Mr. Wood brought for exhibition a fine collection of shells, illustrating the Pontefract district.—Mr. Roebuck exhibited several species of shells taken in the neighbourhood of Harrogate.—Mr. Scholefield exhibited the American mosquito and a fine specimen of *Bombyx cynthia*.—Mr. Denny brought for inspection a quantity of wheat infested by the wheat weevil, and a specimen of the death's-head moth, *A. atropos*.—Mr. Liversedge exhibited a number of insects taken in the immediate neighbourhood, including *Lasiocampa quercus*, *Smerinthus populi*, *Nemeobius lucina*, and *Lycæna alsus*. The next meeting was to be held November 21st, when a paper was to be read by Mr. Acomb, "On geology as a study."

Norwich

Norfolk and Norwich Naturalists' Society, October 25.—The President, the Rev. J. Crompton, in the chair. A most elaborate and interesting paper was read by Mr. F. Kitton, "On Diatomacea and the lower forms of vegetable life as revealed by the microscope." The lecture, for such it may more properly be termed, was illustrated by diagrams, showing some of the most familiar as well as most peculiar forms of Desmids and Diatoms; and at the close Mr. Kitton exhibited a series of very beautiful photomicrographs, of similar objects, executed by Dr. Maddox. The Chairman, in offering to Mr. Kitton the thanks of the Society, and especially of the members present, for the time and labour he had devoted to their instruction, alluded in complimentary terms to the high reputation he had already attained throughout the scientific world, by his persevering researches in this particular branch of natural history; his skill as a microscopist being equalled only by the extreme accuracy of his descriptions of the most intricate and minute organisms. At the request of the meeting Mr. Kitton consented to his paper being published *in extenso* in the Transactions of the Society.

Edinburgh

Royal Physical Society, November 23.—Prof. Duns in the chair. The retiring president, Professor Duns, delivered an address, in which he referred to the early history and past achievements of the Society. A hundred years ago eighteen students of nature banded themselves together for mutual profit in the pursuit of natural science, under the name of the Physical Society. Here is the first list of the ordinary members, Session 1770-1771:—William St. Clair, M.D.; David Young, M.D.; Thomas Melville, Thomas Smith, James French, James Wood, Robert Stewart, Alexander Muir, James Dick, Henry W. Tytler, Malcolm Macqueen, Arthur Taafe, Daniel Gibb, Thomas Thorburn, James Webster, George Home, William Manuel, and William Keir. The names deserve to be brought out of the mists of 1770, and set before the Society in the light of 1870. The period was one well fitted to quicken young and ardent students, and to lead them to long to win their spurs in work closely kindred to that in which others were distinguishing themselves. Eight years previously, Black had made public his theory of Latent Heat, and two years before he had been inducted to the Chemistry Chair in Edinburgh. The influences of the day were bearing in on Hutton's mind, in which "The Theory of the Earth" was shaping itself into compactness and symmetry. Ray's *Synopsis*, Willoughby's *Ornithologia*, Lister's *Mollusca*, and Ellis's *Corallines*, were before the public. But these dealt with British forms. Scotland was still in the rear. Nothing had been done to purpose for Scottish forms, except in the *Scotia Illustrata* of Sibbald, most valuable at the time, no doubt, but also most suggestive of how much still remained to be accomplished. It was in such circumstances the Physical Society began, and more than ten years elapsed before the foundation of the Royal Society of Edinburgh. In 1788 the Physical obtained a Royal Charter, and assumed the name it now bears. Its meetings were held for many years in the Royal Physical Society Hall, Richmond Court, a building which stood on a site now occupied by a chapel. From the outset its influence over working naturalists was great and beneficial, and it ultimately absorbed other kindred associations, which had been at different times set up in Edinburgh. The Chirurgo-Medical, its senior by a few years, joined it in 1788; the Hibernian Medical, in 1799; the Chemical, in 1803; the Natural History, in 1812;

the Didactic, in 1813; and the Wernerian, in 1858. Between 1771 and 1788 many well-known names occur among its list of members—Benjamin Bell, Professors Alexander Munro, J. Hope, Joseph Black, Francis Home, James Gregory, Alexander Hamilton, and W. Hamilton (Glasgow). In 1802, Dr. Barclay and Charles Bell; in 1814, David Brewster. By its union with the Natural History Society it enrolled among its members the botanists, James Edward Smith and Robert Brown, and another, great in almost every department of science, literature, and law, Henry Brougham. Brown's papers on the "Botany of Angus," and on the "Sexes of Plants," are models in this department, and Brougham's on "Thunder" and "Combustion" will well repay a careful perusal. One other notice: in 1828 the Plinian approached the Royal Physical with proposals to unite, and both societies appointed influential committees, with powers to form a union. After much consultation, they reported "that the union of the societies had been admirably accomplished." But the Plinians, after the union was consummated, rued the act, and refused to associate with their lawful head. The Plinian lived on for a season in cold estrangement, and gradually passed into the dark. On the list of ordinary members of the Plinian is the name "Charles Darwin, Shrewsbury, Nov. 26, 1826." The history of the Royal Physical Society is substantially that of Scottish zoology. The latter could not be written without the former. I have only to choose these names from the list of our presidents to make good this remark:—Robert Knox, Captain Thomas Brown, Edward Forbes, Robert K. Greville, James Y. Simpson, John Coldstream, George Wilson, John Goodsir, Alexander Bryson, William Dick, Hugh Miller, Sir John Graham Dalyell, and John Fleming. In these men was embodied the great characteristic of our society. They were all practical naturalists. In November, 1849, Professor Fleming delivered the opening address, in which he urged the expediency of steps being taken by the society to bring before the Government and country the great want of a general national museum for the native products of Scotland, and to bring together the other collections in Edinburgh under one roof. Steps were soon taken in these directions by public bodies and by influential individuals. It again fell to Fleming to give the opening address, in 1855, and he could say—"The gratifying intelligence at last reached us that the Board of Trade had resolved to institute an industrial museum for Scotland in Edinburgh." The Society might claim the merit of one of the first agitations for this great national institution. Dr. Duns passed a high eulogium on the researches of Dr. Strethill Wright on the *Cœlenterata* and *Protozoa*, referring to the sensation produced by the deep-sea dredging report, intimating the growth of chalk in one of the dredged localities. But honour to whom honour. In 1861, this note occurs in Dr. Wright's address to this Society. Referring to the oolite and the chalk, he says: "Similar deposits are now in process of formation over vast areas of sea bottom, especially in the Atlantic, Mediterranean, and Australian seas." Since the Society last met it had lost one of its most distinguished members, Sir James Young Simpson. Dr. Simpson was born at Bathgate, Linlithgowshire, on the 7th June, 1811. He sprang from a family long resident in the district, comfortable in worldly circumstances, and noted for their strong mental powers and outstanding individualities. After being educated at the parish school, where for several years he had for a companion the late Prof. John Reid, of St. Andrews, Simpson entered the Arts course of the University of Edinburgh. He commenced his purely medical studies in 1827, and graduated as M.D. in 1832. Immediately after graduation he was elected President of the Medical Society. In 1833 he petitioned for a seat in this Society, recommended by Edward Forbes. From 1832 to the beginning of 1836, he acted as assistant to Prof. John Thomson, who occupied the Chair of General Pathology in the University. In Session 1839-40 he gave a course of lectures on midwifery, and in 1840 he was elected by the Town Council to the Chair of Midwifery, vacant by the resignation and subsequent demise of Dr. Hamilton. Dr. Simpson died on the evening of the 6th May, 1870. Dr. Duns concluded by some apposite observations on the motives that should incite to natural history studies, and the methods by which they should be pursued.

Botanical Society, July 14.—Sir Walter Elliot, President, in the chair.—1. "On Kashmir Morels." By Mr. M. C. Cooke, India Museum, London. The author remarked, that it has long been known that truffles and morels are found in N. W. India and Kash mir, but no attempt has hitherto been made to determine the species. Some years ago, application was made to the Agricultural and Horticultural Society of the Punjab, and to other sources, for specimens, but without any result. He had, however, lately received, through Dr. J. L. Stewart, a string of dried morels, said to be the morels of Kashmir, and sent by Mr. Baden Powell, of Lahore. This string contains two distinct species, both of them small, and neither of them the *Morchella esculenta* of European markets. The author gave some account of the history of morels as far as known, and concluded by giving scientific descriptions of the supposed two new species from Kashmir. 2. "On the Characters of the Flowers of *Silene maritima* and *Silene inflata*, as regards their Stamens and Pistils." By. Dr. F. Buchanan White. The author had examined 72 plants and 201 flowers of *Silene maritima*; of these, 39 plants were perfectly hermaphrodite, 11 had the stamens abortive, 10 the styles abortive, 11 the styles partly abortive, and 1 with the stamens partly abortive. Of the 201 flowers examined, 122 had three styles and three-celled ovary; 68 had four styles and four-celled ovary; and 11 had five styles and five-celled ovary. 3. "Notes of a Botanical Excursion to the neighbourhood of Perth." By Mr. John Sadler. 4. "Results Obtained from the Cutting and Transplanting of a Plaited Hornbeam Hedge." By Mr. M'Nab. 5. "On the Guachamacan, a poisonous plant growing in the Llanos (plains) of Venezuela." By M. A. Ernst, Caracas.

Glasgow

Geological Society, November 3.—Mr. John Young, Vice-president, in the chair. Mr. James Thomson, F.G.S., submitted to the Society some remains of fish and molluscan life, which he had recently discovered in the neighbouring coal-fields, and which were new at least to the west of Scotland. These were *Acanthoides Wardii*, from Airdrie; *Athyris pisum*, from Brockley; and *Anomia corrugata*, from Dalry. He pointed out the characteristics of these species, and described the relative position of the beds in which their remains had been found. 1. The *Acanthoides* was a well-preserved specimen, showing the dorsal and anal spines in their natural position. This was of some importance, as these spines had frequently been found singly, and could not be referred to any known genus; but this discovery enabled palæontologists to name and classify these ichthyodorulites. This species had also been discovered in the Staffordshire coal-field by Mr. John Ward, and named by Sir Philip Egerton, F.R.S., after its discoverer. It also occurs in the Edinburgh coal-field. The specimen before them had been found near Airdrie, in the upper members of the Clyde coal-measures. 2. *Athyris*. This little fossil occurs at Brockley, Lesmahagow, and Roughwood, Ayrshire. From the resemblance to *Terebratula Saculus*, it had often been mistaken for that shell; but when placed under the microscope the structural characters indicated that it could not be referred to that genus. It had been submitted to Mr. Thomas Davidson, F.R.S., who named it *A. pisum*, from its pea-like form. 3. *Anomia corrugata*. This is the first well-authenticated specimen of Anomia that has been recorded from the Scottish mountain limestone. It is found in a band of shale which underlies the "Linn" limestone, near Dalry.—Mr. D. C. Glen, C.E., gave some notes on the boulder-clay laid open in the excavation now going on for a new dock at Cartsdyke, near Greenock, and referred to the abundance of arctic marine shells and other organisms found embedded in it. The shell-bed seems to occur in a hollow of the boulder-clay, which has been exposed to view by a deep cutting running parallel to the river, or east and west. On the northern side of this cutting, nearest the river, the bed is several feet in thickness; but on the other side it thins out, and finally disappears as we recede from the shore. In the other direction, from east to west, it is seen to abut suddenly against the boulder-clay, and thus occupies a hollow of no great extent, in which, however, an immense number and variety of marine organisms are crowded together, forming one of the richest beds of such clay yet discovered on our western coast. At the same time there was reason to doubt whether the deposit is now found in its natural position, or has not been dug out from some neighbouring part of the shore, and laid down to improve and level the ground, many years ago, in forming the policies where the excavation is being made. On this point, however, he would not express a decided opinion, and other members who had visited the spot were not unanimous regarding it.

DUBLIN

Royal Irish Academy, November 14.—The Rev. Professor Jellett in the chair. The Rev. Maxwell Close read a paper "On M. Delaunay's Views relating to the condition of the Interior of the Earth." The paper was referred to the Council for publication.—Mr. Samuel Ferguson, LL.D., read portions of a paper "On the difficulties attendant on the Transcription of Ogham Legends, and the means of avoiding them." He presented the Academy with a series of casts of Ogham Legends, and pointed out the advantages of them to students of the subject. Dr. Stokes and Professor Ingram congratulated the Academy on this important addition to its collection, and Dr. Ferguson was invited to consider the expediency of issuing engravings of the casts. The reading of the remainder of the paper was postponed to a future meeting.—At a meeting of the Council of the Academy on the 9th inst., it was resolved to recommend to the Academy that Her Majesty's Government be memorialised to use their good offices in order to prevent, as far as possible, any injury during the present siege to the collections in Paris, which are universally acknowledged to be of inestimable value to science, literature, and art. In pursuance of this resolution the following memorial to the Government was adopted on the motion of Dr. Ingram, seconded by Professor Hennessy:—"We, the president and members of the Royal Irish Academy, desire to call the earnest attention of Her Majesty's Government to the irreparable loss which would be sustained by the whole civilised world if the inestimable scientific, literary, and other collections of Paris should be destroyed or seriously injured during the siege. That city contains galleries stored with treasures of art, libraries rich in every species of literary monument, and scientific museums which are amongst the foremost in their several kinds. These collections represent the accumulated labours of many generations, and are, in truth, the property not of France only but of the whole civilised world. Many of the objects contained in them, if once allowed to perish, no subsequent exertion could ever replace. The fate of the library at Strasburg shows that these priceless collections are in real and imminent peril from the operations of the war. It is not for us to pronounce any opinion on the merits of the present lamentable struggle, or on the conduct of either of the contending parties; but as members of a body having for its object the cultivation of science, literature, and archæology, we protest, in the name of the intellectual interests of humanity, against the destruction of these collections; and we respectfully call upon Her Majesty's Government to use their utmost efforts for their preservation, by impressing on the belligerents the duty of taking every possible precaution for their protection from the dangers to which they are likely to be exposed."

Royal Geological Society of Ireland.—W. Stokes, F.R.S., in the chair. The Rev. Prof. Haughton, F.R.S., read a paper "On the amount of horizontal thrust produced by the secular cooling of the earth, and its effect in producing continents and seas." In the discussion which followed the reading of this paper, Professor Hull, Rev. Maxwell Close, and Mr. William Ogilby, took part. Professor Macalister, hon. sec., exhibited a collection of volcanic rocks and of fossils from South Italy, presented by Prof. Guiscardi and Mr. R. Mallet, also a collection of fossil Devonian Plants from Nova Scotia, presented by Principal Dawson.

BERLIN

Royal Prussian Academy of Sciences, July 14.—Dr. A. W. Hofmann read a memoir on the Aromatic Cyanates, containing investigations on derivatives of the phenyle, tolyle, xylyle, and naphtyle series.

July 25.—M. Kummer read a paper on the Algebraic Systems of the third order—. Prof. W. Peters read descriptions of New Species of Shrews from the British Museum. The species were *Crocidura retusa*, from Ceylon, *C. fœtida* and *C. doriæ*, from Borneo, *C. monticola*, from Java, *C. microtis*, from Hong Kong, and *C. gracilipes*, from Madagascar, and belonging to the subgenus *Pachyura*, *C. waldemaris*, from Bengal, *C. ceylanica*, and *C. media*, from Ceylon, *C. sumatrana*, from Sumatra, *C. fuscipes*, from Singapore and Java, and *C. luzoniensis*, from Manilla.—Dr. Hofmann read an account of various investigations relating to the action of cyanogen upon aniline and triphenylguanidine, to a new class of cyanic ethers, to a new mode of formation of the isonitriles, to tests for cyanuric acid and chloroform, to the diagnosis of primary, secondary, and tertiary amines, to the knowledge of phenylxanthogenamide, to the action of acetic acid upon phenylsenföl, to the history of the ethylene bases, to the knowledge of aldehyde-green, and to the molecular volumes of chinone.

PHILADELPHIA

American Philosophical Society, Oct. 21.—Prof. Cope read a paper "On the Osteology of *Megaptera bellicosa*." He stated that this species of whale was one of the few whalebone whales of economic value found within the tropics, being the object of pursuit in the Caribbean Sea. Having received a skeleton from the island of St. Bartholomew, West Indies, he presented a detailed account of its structure. He pointed out important points by which it differed from the known species of *Megaptera*, among others in the form of the mandible and of the nasal bones.—Dr. George Emerson read a paper on the part taken many years ago by the American Philosophical Society and Franklin Institute of Philadelphia in establishing stations for meteorological observations in Pennsylvania, detailing the arrangements adopted by them for procuring a full series of observations at fifty-two points in the State.

BOOKS RECEIVED

ENGLISH.—Odd Showers, or an Explanation of the Rain: Carriber (Kerby).—Our Feathered Companions: Rev. T. Jackson (Partridge).

THE ECLIPSE EXPEDITION

BEFORE this reaches the hands of our readers, both sections of the English Government Eclipse Expedition will be on their way, the one to Spain and Algiers, the other to Sicily. The article in our last number will have given a general idea of the work to be done, and we think it will be admitted that seldom has so much work been laid out to be accomplished in a brief two minutes. To choose the right men for so important an investigation in a scientific point of view has been no easy task; but the list may now be looked on with satisfaction as comprising men of known ability, and of tried powers of observation in the various departments of Science concerned. Astronomy, chemistry, spectroscopy, photography, pure physics, are all worthily represented; and from our Paris intelligence this week it will be seen that there is good hope of M. Janssen being able to leave Paris to join in the Expedition.

We can now only wish for both parties that the elements will be propitious for the work they have undertaken. The time during which the observations can be made is so short that the most careful arrangements will be necessary to utilise the observing powers of every member of the party. Each will have his work definitely laid out for him. On the performance of the assigned duty without regard to other phenomena which come within the sphere of another man's work, will much of the success of the Expedition depend.

But scarcely less important than the arrangements at the moment of the eclipse, have been those of the Organising Committee, which had the charge of the preparations for the Expedition. The unfortunate delay which took place in ascertaining the intentions of the Government, threw on this Committee, after that intention was known, an amount of work compressed into the space of a few weeks, which ought to have extended over as many months. It was only in the first week in November that a definite assurance was received that an application for money and ships for the purposes of the expedition would be likely to be successful. The work to be accomplished by the Committee between that time and the first week in December, was such as those experienced in such matters might well shrink from; but, thanks to one or two individuals who had the advance of science at heart before anything else, the work has been done, and, what is more, has been well done. To Prof. Stokes in particular the thanks of the scientific world are due, for the untiring assiduity with which he has laboured to bring the affair to a successful issue.

If there is one cause for regret in the programme of arrangements, it is the absence of any one name among the observers who are going out, who can be said to directly represent the Government. It is a Government expedition, undertaken with the assistance of public money and ships belonging to the nation; and it would have been right and fitting to have seen at the head of it one of the Government astronomers, rather than that all the labour of the organisation and all the credit of the observations, should they be successful, should fall to the lot of private persons. This expedition will, indeed, form a conclusive argument against those who have held that if Government hold out a helping hand to Science, this will act as a bar to all private enterprise. Had the Government held back altogether from offering their assistance, no English expedition would have been organised; individual astronomers who felt sufficient enthusiasm to give up their time, and spend their money in furthering the ends of Science, would have been compelled to avail themselves of the generous and munificent offers of assistance from the American Government. Need we say in what light this would have been regarded by contemporary science and by future historians? Government having once stepped forward, and assumed its rightful position, a stimulus was thereby given to private enterprise; every individual concerned felt that not only the interests of Science, but the honour of his country was at stake, in doing his part towards ensuring a successful result; and probably never has an expedition been better organised, and started under happier auspices, notwithstanding what has been said to the contrary in one of the daily papers, which has evidently been misled by those who have a purpose to serve in abusing the Committee.

Now that the Government has put its hand to the work, we are bound to say it has done so in no grudging spirit. More has already been done than the promoters of the Expedition were at first given to expect. Not only has the *Urgent* been placed at their disposal, to carry the Spanish and Algerian party from Portsmouth to their destination, but a despatch-boat, the *Psyche*, is told off for the Sicilian expedition. All the foreign Governments concerned appear determined to emulate this good will; the arrangements of that of Spain we have already published. There is reason to hope that the necessary apparatus will pass through every custom-house, duty free, without the slightest impediment. It is hoped that the Sicily party may combine with that sent by the American Government, and may do their work and publish their results in concert.

Our readers need hardly be reminded of the special object which it is hoped will be accomplished by the present expedition: the settling for ever of the vexed questions concerning the luminous appearance visible in total eclipses, known as the Corona, both as to its actual locality and its constitution, which still have to be settled, notwithstanding some hard writing to the contrary. In all these observations the utmost nicety of observation will be required, and some ingenious and novel contrivances will be employed for the determination.

We shall take the earliest opportunity of placing the results before our readers. We have taken means to have a report sent to us by telegraph from every station, and shall hope to be able to summarise them in our issue of the 29th inst. These early reports will be the more valuable, as up to the present time we have no official account of the observations taken in Spain during the total eclipse of 1860. With the exception of Mr. Warren De La Rue's observations, published by himself, no results of that expedition have yet been made known to the public.

We have now only to wish the Eclipse Expedition, and every member of it, a pleasant and prosperous voyage, and a happy return to England with the consciousness of having contributed something to the progress of scientific investigation.

B.

HAECKEL'S NATURAL HISTORY OF CREATION

Natürliche Schöpfungs-Geschichte. Von Dr. Ernst Haeckel. 2te Auflage. (Berlin: Reimer, 1870. London: Williams and Norgate.)

WERE there any need of evidence to show how busy in the happier times of peace the German public was with Darwinism and general Natural History topics, it would be amply supplied by the history of this work, the preface to the first edition of which was written in August 1868, and the second edition of which is now before us. The work is, broadly speaking, a popular sketch, not so much of the Darwinian theory, as of Haeckel's extension of that theory; in many respects it is a new "Vestiges of Creation," the old question being viewed from a new stand-point, and the treatment of it adapted to new feelings and new times. The old work was modestly entitled "Vestiges;" Prof. Haeckel calls his a History; and indeed a detailed comparison of the two would bring out in a wonderfully vivid manner both the progress of zoological inquiry and the change in zoological temper which has taken place in the interval between the dates of their publication.

The relation of Prof. Haeckel's extended views to the original theory of Mr. Darwin is very well indicated in a few lines of the preface to the second edition. "Darwinism is neither the beginning nor the end of the theory of evolution; it is far away removed from tending to narrow or to fix an absolute limit to further inquiry. Just as every important onward step in science becomes at once the starting-point of many new lines of advance, so Darwin's theory of selection gives immediate rise to many large extensions of the general theory of evolution; and of these my Phylogenic theories are some of the first to hand. When, then, the orthodox Darwinians cast at me the reproach that 'I go too far,' that 'I out-Darwin Darwin,' that 'by my Radicalism I do harm to true Darwinism,' I see in all such reproaches nothing but an unwilling confession that I have extended the evolution theory away and beyond the limits within which Darwin investigated the question, and have not been afraid to carry it out to its grand consequences."

In the early edition, the first six lectures are devoted to a historical sketch of the evolution theory; the creation theories of Linnæus, Cuvier, and Agassiz, and the evolution theories of Goethe and Oken, of Kant and Lamark, of Lyell and Darwin being taken as landmarks. In the second edition these chapters have been somewhat enlarged and improved, but on the whole stand very much as they were. The next five lectures (7—11) form a general exposition of the theory of Natural Selection, with discussions on heredity, adaptation, and the struggle for existence. In the second edition these chapters remain almost exactly as in the first. The same may be said of the twelfth lecture, in which a sketch is given of Ontogeny, or the development of the individual, and a comparison made between it and Phylogeny, or the development of the kind or species—in other words, Genealogy. The two succeeding chapters discuss rapidly the cosmic history of the globe, the primordial differentiation of living from lifeless things, and contains, under the title of Periods of Creation, a short sketch of Palæontology. Between these two chapters the author has, in the second edition, introduced a totally new chapter on what he calls Chorology, *i.e.* the theory of migrations, in which he discusses the influence of migration on species, the causes of migration, the effect of changes of climate, and the question of centres of creation, and points out the probable results of the Glacial epoch. The palæontological sketch is also much changed in the second edition, the "theory of ante-periods," which has found but little favour with geologists, being, though unwillingly, withdrawn.

The remainder of the volume, nearly half, is taken up with a concrete history of creation, *i.e.* with an account of how, and by what steps, all kinds of plants and animals have grown out of the primordial moners, those first existing living things which were, according to Haeckel, neither plants nor animals, but belonged to a third kingdom of Protista. This part of the work therefore is a descriptive genealogy of all living beings, the pedigree of each kind of creature being made out, or rather conjectured out, as far as present knowledge will allow.

In the second edition, as might have been anticipated, the genealogies are very much extended, and given with much greater detail than in the first; in particular, there is a new whole chapter on the migration and dispersion of mankind, and on the species and races of men. The results of phylogenic speculation or inquiry are graphically shown in elaborate genealogical trees; and a new large plate shows at one glance how all races of men have probably spread from a hypothetical paradise once situate in the great continent of Lemuria, now sunk below the waves of the Indian Ocean.

The result of criticism is shown in some few changes in the several pedigrees, but on the whole these differ in the second edition very little from what they were in the first. The Halisaurians, for instance, have been brought back to the amphibians, and the Dinosauria have been brought nearer to the birds; in fact, the whole arrangement of the Reptiles has been a good deal upset. Otherwise the still larger changes suggested by Prof. Huxley and other anatomists, are referred to, but not admitted.

In the first edition the title-page was disfigured by being opposed to a picture of heads of men and monkeys, which was at once absurdly horrible and theatrically grotesque, without any redeeming feature either artistic or scientific. In the second edition the heads have been increased from twelve to twenty-four, but their quality remains the same. As a set-off against this, however, we are presented with two really beautiful and very instructive plates of the development of several kinds of crustaceans and echinoderms, and one comparing the development of a tunicate and amphioxus. There is also a large comparative view, well worth studying, of the embryos of the four vertebrate classes at two different epochs of their development.

We have, in the above, attempted to give a general idea of what the book is, and how the second edition differs from the first, rather than to enter into any criticism. The first edition has already received the ablest criticism this country could give. We will venture, however, to make one reflection. Had the book been written for scientific men, it would have been read by some with delight, by others with feelings of fretfulness and worry, but by all with more or less of profit. Addressed as it is, however, to an intelligent and cultivated, but still to a general and unlearned public, prone to receive fanciful analogies as real reductions to simpler laws, and to confound together fond imaginings with sound and fruitful hypotheses, we very much doubt whether it may not turn out to be an engine rather of mischief than of good. Genealogies there must be, doubtless, and many, doubtless, also may in time be made out. In cases like the pedigree of the horse, the evidence already seems wonderfully strong; and it would be simple presumption to fix a limit beyond which we cannot hope for success. Still, by their nature, genealogies are like castles of cards in the shape of inverted pyramids, with each tier less safe and less sound than the one above it. A very little memoir may disturb one of the lower stages, and then a whole pile comes down with a run. They are not the kind of things to put before learners as the strongholds of science. Some readers would learn in the first half of this volume to love Darwinism better than biology, and before they had finished the second half, would love Haeckel better than either. Others would pass rapidly through a disbelief in Haeckel and distrust of Darwin to a state of complete doubt about biology in general. Worst of all would be the effect on such minds as that of a speaker at one of the meetings of the Biological Section of the British Association at Liverpool, who said he had believed for many years in spontaneous generation, in natural selection, in the evolution theory, and in most views of a similar kind, and who seemed ready to believe anything and everything except the old truth, that truth is very hard to get, but very precious when it is gotten.

M. F.

DEFECTS IN GENERAL EDUCATION

On Some Defects in General Education. Being the Hunterian Oration of the Royal College of Surgeons for 1869. By Richard Quain, F.R.S. (London: Macmillan and Co. 1870.)

DR. QUAIN begins the present lecture with a pleasant and suggestive sketch of the career and genius of Hunter, but the greater part of it is taken up with the subject indicated in the title. The point to which most attention is naturally directed is the predominance of classics in the present system of education. Against this Dr. Quain protests with all the ardour that we expect in a man imbued with the best scientific ideas of his time. In the first place, he insists that the study of our own language and literature should hold a much more important place in the education of our youth than is actually assigned to it. He thinks it monstrous that men should be carefully taught to read Latin and Greek, and be left in almost total ignorance of the history of their own speech, with scarcely any real power of using it, and without the smallest insight into the true spirit of one of the richest and most extensive literatures in the world. Above all, however, Dr. Quain urges that Science should become the staple element of modern education. On the ground of mere expediency, he points out, rich and poor ought alike to be taught Science, for it gives the former a truer conception of the duties which attach to property, and the latter it enables to improve their position. But what is even more important, Science imparts to those who devote themselves to it the freest and largest culture; and it is grossly irreligious to talk reverently of a Creator, and yet to refuse to seize every opportunity to become better acquainted with the Creation. "If the instructors of the young in schools believe, if parents believe, that the things of this world are in truth the work of the Creator ought not that belief, without anything further, to settle the question for them? Ought not these 'glorious works' to be acknowledged as subjects for diligent study, not disregarded as they are now?" Another fault in our educational arrangements to which Dr. Quain refers is the excessive devotion to athletic sports which at present prevails. This, he thinks, arises from the repulsive nature of the chief subjects of study at our schools and universities, and would probably come right if the intellectual tastes and propensities of every order of mind were more carefully studied and gratified. The lecturer also protests against the dangerous extent to which we have carried the competitive system at the present day. With all the best writers on the subject—Mr. Matthew Arnold in particular—he believes that excessive competition is the reverse of favourable to true culture; that it renders anything like real study distasteful, and produces in the end narrow and superficial minds. He suggests that it might be well, as in Germany, to have for boys leaving school one general examination, which it would be necessary to pass for entrance to the universities to the professions, and to the public services. For this examination there would be no special preparation; it would only serve as a test of the general culture derived during a series of years from the training of skilled teachers. Afterwards the student ought to be allowed to consult his own tastes in the choice of subjects of study, The other matters of which Dr. Quain speaks, are the necessity for a higher order of masters in our national schools, and the absurdity of mixing up with strictly professional training in medical schools instruction in physics, chemistry, and botany. We hope that so thorough and exhaustive an exposure of the weak points in our educational system, coming as it does from so high an authority, will not be without its effect in quarters where there is the power, if only there was the will, to bring about a more satisfactory state of things.

OUR BOOK SHELF

The Natural History of Commerce. By John Yeats, LL.D. (London: Cassell, Petter, and Galpin, 1870.)

THE design of this book is excellent; and it has, on the whole, been well carried out. The author is well known as the principal of a large "middle-class" school, who has long recognised the claims of Science as an essential item in the education of an English gentleman or merchant. And the information contained in this volume is exactly such as ought to be familiar to everyone who lays claim to the advantages of a liberal education. We are afraid, however, that, as a matter of fact, it will be found that the "Natural History of Commerce" is a *terra incognita*, especially to those engaged in commercial pursuits, who might often derive, not only pleasure, but, what is perhaps more to the point, profit, from some acquaintance with it. The work is divided into four parts. In the first we have commercial products treated from a geographical point of view; the different botanical zones of Meyen are defined; and the principal natural products described of Britain, Continental Europe, and the other quarters of the globe, with a supplementary chapter on Nature and Man as agents of change. The second part is descriptive of the commercial products of the Vegetable Kingdom, in which Meyen's plan appears again to have been followed in the main; it is subdivided into Food Plants, and Industrial and Medicinal Plants. In the third part we have, in like manner, the commercial products of the Animal Kingdom; and, in the fourth, raw mineral products. The comments which we have to make are almost confined to errors of omission which can be readily rectified in future editions. We regret to see still retained the antiquated classification of the Animal Kingdom into Vertebrata, Mollusca, Annulosa, Radiata, and Protozoa. The sentence by which (p. 260) the porcupine and the ant-eater are made members of the order Monotremata, is no doubt merely an oversight. Among food plants, it is strange to find no mention made of the potato, nor, indeed, of any of our culinary vegetables, the cabbage, turnip, or carrot, with the single exception of the onion! We demur to the assertion that the morel is "one of the few fungi found in this country which may be eaten with safety;" among these few we do not understand why the truffle and the morel only are given, the mushroom not being even alluded to. Indeed, the whole subject of Vegetable Products requires revision, many being entirely omitted of much greater importance than others to which considerable space is allotted. Among Industrial Plants, for instance, we should expect to find some description of the numerous fibres now used in the manufacture of paper, the esparto-grass, different kinds of wood, &c., which are daily becoming more important articles of commerce. An exceedingly useful vocabulary is appended, containing the names of natural productions in the principal European and Oriental languages; and the volume may be safely recommended as containing an immense mass of useful information on a very important subject.

Record of American Entomology for the year 1869. Edited by A. S. Packard, Jun., M.D., 8vo. (Salem, 1870. London: Williams & Norgate.)

THIS is the second annual analysis of the literature of American Entomology which has been published under the care of Dr. Packard. It must be gratifying to entomologists to find that their science is so popular in the United States as to render the production of such a work at all feasible, and we can only hope that the Editor may receive sufficient support to enable him not only to continue it in its present form, but even to enlarge it and make it still more useful. Of course, with the general entomologist, this Record can never take the place of the entomological portion of the *Zoological Record* which has been brought out in this country since 1865, but it is of the greatest value in giving the European naturalist intimations of papers and descriptions published in those out-of-the-way American periodicals which rarely fall into his hands.

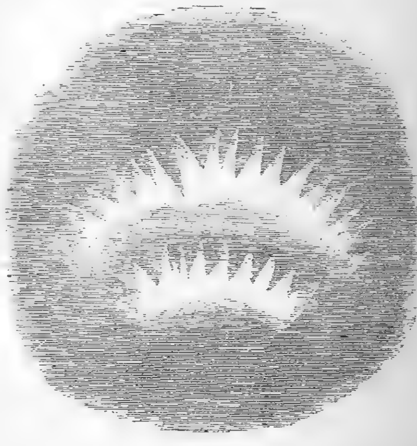
The Aurora Borealis by Daylight

I HAVE been expecting ever since the great display of Tuesday, Oct. 25, to see some statement that the Aurora was visible on the afternoon of that day. I was in Huntingdonshire, about four miles from Kimbolton, at the time, and being out of doors at half-past four P.M., saw a remarkable pale luminous appearance some 25° above the horizon and almost due east. At this point there were two arcs of faint white lines, one above the other, both radiating outwards with a number of short points. The breadth of the upper arc (which was rather the widest) might be from twelve to twenty times the apparent diameter of the moon. It was of course broad daylight at the time, and the sky was perfectly clear and cloudless for a long distance round these patches of light. They were visible for at least ten minutes, brighter and fainter alternately, and were seen by a friend as well as myself. I was unfortunately called away, and prevented from watching them while the sky became darker. After dark (at 5.30)



they had disappeared, but the dark irregular circle mentioned by Mr. Grove, from which the streamers radiated, was extremely conspicuous. It did not strike me at the time that the appearance at 4.30 was likely to have any special interest. But as it seems that the greatest disturbance of the telegraphs happened before the *evening* display of the aurora, it may perhaps be of use to record that it was also visible in the latter part of the afternoon.

26, Finsbury Place, E.C. JAMES CUBITT

The Spectrum of the Aurora

THE following observations on the Spectrum of the Aurora were made by Mr. Alvan Clark, Jun., in the neighbourhood of Boston, on the evening of October 24. He used a chemical spectroscope of the ordinary form, with one prism, and photographed scale illuminated with a lamp. Four lines were seen at the points marked 61, 68, 80, and 98. To reduce these to wave-lengths, the next day I measured the lines C, D, E, b, F, and G with the same instrument, and deduced the annexed table:—

Line.	Reading	Wave-length	Assumed Line.	Comments.	Error.
C	49·1	656			
D	57·8	589			
(1)	61	569	557	Common Aurora Line	—·2
(2)	68	532	531·6	Corona Line ?	+·1
E	69	527			
b	71·2	517			
F	79·7	486			
(3)	80	485	486	F Hydrogen.	—·3
(4)	98	435	434	G "	+·6
G	100·5	431·2			

The first column gives the name of the line; the second the readings on the scale; the third its wave-length, obtained from Angström's chart, and by interpolation; the fourth the wave-length of the line with which these lines are supposed to be identical. The fifth column gives the name of this line, and the sixth the error in parts of the scale. The first measure is evidently wrong, and should probably have been 63. For the other three, however, the agreement is remarkable, two coming close to F and G of hydrogen, the other to the line observed by Professor Young in the solar corona. The lines C and F having already been observed, the discovery of the line G seems to render certain the existence of this gas in the Aurora. The common methods of interpolation were not available for computing the wave-lengths of column three, on account of the large interval between the lines. A curve was therefore constructed, in which vertical distances represented scale-readings, and horizontal distances the square of the reciprocal of the wave-lengths. This, by the formula of Cauchy, should be very nearly a straight line, giving, consequently, results of great accuracy.

EDWARD C. PICKERING

ON the evening of Monday, October 24, a very remarkable auroral display was observed in New York City. In the north at first was an obscure segment, low towards the horizon, surmounted by a pale glow of light. Later, this was replaced by an extensive manifestation of beautiful streamers.

But the most notable part of the phenomenon was a band of brilliant red light, varying in its different parts constantly throughout the evening, in brilliancy, definition, and breadth, but in general some ten degrees wide. It was seen early in the evening, and could be traced from within fifteen degrees of the horizon in the east and the west, extending entirely across the sky, south of the Zenith.

The position of this rosy band viewed from the south-east corner of the Central Park, was from $8\frac{1}{4}$ to $8\frac{1}{2}$ p.m., New York City mean time, about as follows.

In the east, just above the horizon, passing almost centrally, and diagonally through the figure of *Cetus*, say between δ and ζ Ceti; thence going westward it lay between *Piscis occidentalis* and γ *Aquarii*, and between *Altair* and *Delphinus*, often expanding in width beyond these boundaries. Thence it extended westward to the stars in the heads of Hercules and Serpentarius nearly to the horizon.

In all its splendid variations throughout the evening, it maintained its position in regard to the horizon of the observer standing in the locality before mentioned, the diurnal motion of the earth carrying the stars past it.

On the following evening the exhibition of this red band, in the same position, was at least equally pronounced; but without any decided boreal light, so far as I have noticed or learned.

I would also here mention the very brilliant display of variously tinted auroral streamers which engaged the admiration of members of the American Association for the Advancement of Science, as they returned by the steamer on the Hudson to the city of Troy, from their visit to Albany, from ten to eleven o'clock on the evening of Friday, August 19, 1870.

JAMES HYATT

Honey Brook, Stanfordville P.O., New York

Early Mentions of the Aurora Borealis

YOUR correspondent, Mr. Earwaker, should have mentioned that the list of appearances of the Aurora Borealis given in M. de Mairan's work is chiefly derived from another enumeration in Prof. Frobes's "Nova et Antiqua Luminis atque Auroræ Borealis Spectacula," Helmstadii, 1739. On reference to this list it immediately appears that it is very little to be relied upon for displays previous to the year 1707 or thereabouts. Some of the appearances recorded rest on no good authority, others were obviously meteoric; some occurred within the Arctic circles, others are entered twice over from inadvertence, or a neglect to allow for the difference of style; more than twenty are recorded on the authority of the meteorological diary kept at Breslau by Grebner, who in fact says nothing more than that on those occasions the night was somewhat bright (*sublustris*). When the necessary deductions on these accounts have been made, it will be found that the infrequency of the phenomena prior to 1707, and its extraordinary development since that date, are well-established facts. They are strongly insisted upon by M. de Mairan himself, who does not produce more than five instances of the aurora in France during the whole of the seventeenth century, and shows from the evidence of a missionary that it was unknown or forgotten in China until 1718. All contemporary notices prior to about this period, attest the astonishment with which it was regarded.

From the following curious passage in Sirr's "Ceylon and the Cingalese" (vol. ii. p. 117), it would appear that the aurora, or something resembling it, is occasionally visible in Ceylon:—

"There is a heavenly phenomenon which appears occasionally in Ceylon, called by the natives Buddha lights; this faintly resembles the Northern Lights, and is extremely resplendent. The priests declare this to be a sign of Buddha's displeasure when his followers have become sinful in the extreme, and that the light appears over the wihare, from whence the priests suppose the phenomenon to emanate, where those who have committed the sin which has aroused the god's anger last worshipped."

London, November 19 R. G.

IN many parts of Ireland a scarlet aurora is supposed to be a "shower of blood." In 1854 while stationed at Bearhaven, County Cork, a scarlet aurora that then appeared was said to be the blood of the people that were slain at Balaclava. About two years ago, while driving between Oughterard and Clifden, at two o'clock in the morning, there was a magnificent scarlet aurora (by far the most brilliant I ever saw), on which the car-driver remarked, "I wonder, can that be the blood of the Americans?" The late aurora is said to be the blood of the Frenchmen.

In the old Annals showers of blood are recorded at different times, always in connection with a great battle or the murder of some great chief. The earliest I can remember is that of A.D. 688, in the "Annals of Cloonmacnoise," after a battle of the Leinster-men and Os-ory-men (now in the King's County, but formerly in Munster), wherein Foylcher O'Moyloyer was slain. This battle and shower of blood in the "Annals of the Four Masters," is said to have happened in the year A.D. 690. These Annals also mention that butter was turned into the colour of blood and a wolf was heard to speak; while the Annals of Tighernach place the battle in A.D. 693, and say that the blood flowed in streams for three days and three nights. During the aurora I saw about two years ago, and the two nights that the last aurora was seen here, the lakes and rivers looked to be full of blood. Therefore I should imagine the aurora of 688 must have lasted three nights, and that the people who saw it and recorded it must have had butter for supper the night it was seen, which reflected the colour.

G. HENRY KINAHAN

Geological Survey of Ireland,
Connemara, Nov. 26

Prismatic Structure in Ice

THE following extracts from a letter from Mr. Langton (whose name was, unfortunately, misread as Langters in sending his former letter to the press) may interest others as much as it has done myself, if space can be found for it in your columns. In that case, perhaps, you will kindly allow me to say a few words in reply on a future occasion.

St. John's College, Cambridge T. G. BONNEY

"I admit with you that the prismatic structure of ice on the point of melting does not appear to have any connection with the hexagonal crystals in which it is formed; and that the great analogy between the conditions of ice in that state and of igneous rocks, and I may add of clay in the process of desiccation, seems to point to contraction as the common cause. But then arises the question whether ice really does contract as it approaches the melting-point, as we know that most melted mineral matter does on cooling, and clay on drying. I am quite willing to admit that it may do so, and that, as you observe, its demeanour at a point about 32° F. has not been accurately ascertained; but if so, the fact should first be determined from independent observations before drawing conclusions from it. I am willing also to admit that I spoke loosely in my former letter when I said that the air bubbles in the process of freezing seemed to be formed in vertical lines. My object, in the concluding sentence of that letter, was to express a doubt as to there being any such contraction as you suppose on the ice approaching the melting-point, and to point out the lines of air bubbles as being the immediate cause of the structure of rotten ice. I did not then go into the origin of the bubbles, or into the cause of their being thus found in vertical lines. It is difficult to suppose that they were originally formed in those lines, for though it seems natural that the air, which is always contained in water, should be excluded on its crystallising, there does not appear to be any sufficient reason why the bubble excluded to-day should be placed exactly under that formed yesterday. Upon reviewing the whole question, I am induced to think that, as will often happen, we were both right and both wrong: that you were right in attributing the prismatic structure originally to contraction, but wrong in supposing that contraction to be caused by an increase of temperature on the approach of the thaw, and that I was right in attributing the final break-up into prisms to the liquefaction spreading in every direction from the lines of air bubbles, but wrong in speaking of them as if they had originally been formed in those lines. We need not resort to a hypothetical contraction about the melting-point; we have a *vera causa* in accesses of cold, which will give you the desired contraction, and me my vertical lines of air bubbles. The true explanation I take to be as follows.

"After the ice has formed, and severe cold follows, it will contract, and probably equally in all directions. There is no impediment to its shrinking perpendicularly, as the whole sheet would then only be somewhat reduced in thickness; but the ice is entangled with the shores, and the whole sheet cannot contract horizontally, but relieves itself by a number of minute cracks. These are easily seen on the surface of glare ice, but one can hardly imagine that they do not more or less spread through the whole substance, and in your first letter you seem to say that you have noticed this after severe frosts. If then an air bubble comes near any such crack, it would seem natural that the direction of the crack should be diverted towards it. In fact the air bubbles, being weak points, would in a great measure determine the direction of these small fissures. Water would insinuate itself into them from below, carrying the air bubbles with it, which, upon the whole freezing, would not necessarily be exactly where they were before. A repetition of this process at frequent intervals during the winter would cause a rearrangement of the air bubbles, which one would naturally expect to find from this cause in more or less vertical lines. According to this explanation the prismatic structure would set almost from the first formation of the ice. The air bubbles would from the first be the indication of the direction of former fissures, and the lines which would determine that of new ones. As long as severe frosts continued, all other indications of the structure would be obliterated, but, as the temperature approached the melting-point, these lines of bubbles, as they formerly determined the direction of the fissures, would now be the weak points at which the thaw would commence, pervading the whole mass.

"This explanation seems to supply everything that is wanted, and, upon looking back at your original letter, I am rather surprised, from the facts you mention, that you should have missed it. You say, 'I have seen it several times—in fact, *after every severe frost*.' This I have no doubt is correct; but why, then, do you say, lower down, that 'this finer structure may be found, if looked for, in *every tolerably gradual thaw*'? Again, you say that on one occasion you found the structure obliterated internally, 'except where some vertical lines of air bubbles marked the position of a tube or joint.' This exactly corresponds with what I have above supposed would be the process.

"Still, there are several points upon which more exact observations should be made before one can speak with any certainty upon the subject.

"1. Does ice contract on approaching 32° F.?

"2. Do air bubbles form from the first in vertical lines?

"3. Is there any indication, as the winter advances, of a rearrangement of the bubbles, as that they run into each other, and get more and more ranged in vertical lines?

"4. Is there any indication in the earlier stages of the ice, that, after a night's hard frost, the cracks seen on the surface spread through its substance? And if so, to what extent do they follow the lines of air bubbles?

"5. If a block of ice is cut early in the winter, before the prismatic structure from contraction with cold has commenced in any noticeable degree, and when it is no longer in a position in shrinking to crack in one direction more than another, to what extent does that structure afterwards develop itself?

"As there has been this one point in the behaviour of ice in which we have both taken an interest, I am induced to mention some other peculiarities which have come under my notice, with regard to some of which I have not even attempted to suggest an explanation. Several years ago I lived on the shores of a lake in the backwoods, and as in those early days the ice in winter and a canoe in summer formed one's only means of locomotion, one naturally thought a good deal about ice in its various stages of formation and decomposition. I lived about two miles below the head of the lake, where a river fell into it, upon which was a considerable fall, and which connected it with another much deeper lake, about a mile above. The effect of the stream was felt for a considerable distance into this lower lake, which was narrow at its head, and the ice was never safe there; indeed, excepting in the very severest frosts, there was as it were a bay of open water extending into the ice almost as far down as my house. But when the ice first formed in the fall it invariably took over the whole lake, even on that part which was afterwards open water during almost the whole winter. Indeed, upon one occasion, upon getting up in the morning I was astonished to see ice formed exactly on that part which was usually open water, whilst the rest of the lake, which was usually closed, had no ice upon it at all. Very soon after the sun rose that ice disappeared and the lake did not freeze over for a week after. The first ice, which always formed over the whole lake, would generally remain till there was a fall of snow on it, soon after which it would disappear where the effect of the stream was felt. The first winter I was there I nearly suffered from ignorance of this habit of the ice. I had occasion to cross the lake, which had been closed for some days, and had received a pretty thick coating of snow in the meantime, and, knowing that the ice must be pretty thin, I took the precaution to wear snow shoes. After a while I felt a peculiar sinking of the snow shoes, and observed that the track filled with water, and upon feeling with a stick I carried, I found no resistance of ice at all. I was, in fact, walking upon little more than a cake of snow. You may imagine that I at once made a little circuit and did not stop till my stick encountered good ice, and an hour or two afterwards that part of the lake was open water. Now I think I can explain this peculiarity of the early formation of ice where no ice remained during much colder weather in the winter. I take it that the whole surface, at least, of the water in my lake, which was rather a shallow one, had been reduced to 32° F., or nearly so, and that on a very cold night the water from above, being thoroughly exposed to the cold in coming over the fall, had been reduced even lower, so that when it reached the comparative quiet of the lake, where it naturally floated on the surface, it became ice for a short time that morning I spoke of, though it could not long maintain that condition. So also on ordinary occasions, when all the lower lake was ready to freeze, the water, thoroughly cooled at the fall, would freeze also, although the lake above had not yet been frozen over. At the foot of the upper lake, immediately above the fall, was a very shallow bar, so that the only part of the upper water which would come over would be the coldest layer on the top. But after the upper lake had frozen over also, and had received its coating of snow, very little more cold would penetrate to reduce the temperature of the surface, and the lake being very deep, and receiving fresh accessions of heat from below, the water would soon get considerably above the freezing-point, and with the aid of the friction of the stream would thaw away the snow-covered ice below with which it first came in contact. One is inclined to ask why the complete exposure of the water to the cold in coming over the fall, which I have supposed to reduce the temperature so much in the beginning of winter, had not the same effect in the severer cold afterwards; but the water which came from under the snow-covered ice would probably be much warmer than that which formerly came from the surface of the open water, and moreover the spray soon formed ice, which gradually crept over the shallower parts of the fall at its edges, and the exposure and its cooling effect may not have been as complete as at first. I cannot say that I am altogether satisfied with my explanation of the curious anomaly that a part of the lake would freeze over at a temperature of 20°, which would remain open when it was far below zero; but such are undoubtedly the facts.

"If there was this anomaly in the first formation of the ice, its sudden disappearance in the spring, which I mentioned in my former letter as giving rise to the popular prejudice that it sinks, was almost equally astonishing. Upon one occasion the ice was evidently in the last stage of decomposition, and I had got my canoe ready for a journey in the morning, when I fully expected the lake would be open; but before starting, I wanted to go to the two or three houses at the fall, which we dignified with the name of a village. Although the lake at my landing was an unbroken sheet of honeycombed ice, which had even borne me early in the morning, the open water extended to a point about half a mile above me, and I determined to carry my canoe so far through the woods. I cannot have been a quarter of an hour in doing so, but when I launched my canoe beyond the point, there was not a vestige of ice down as far as my landing, though I still saw it across the whole lake a little farther down. Being anxious to see the process of the actual disappearance, I turned my canoe down the lake, and paddled as fast as

I could; but long before I could get to where I had seen the ice, the whole lake as far as my view extended was open water. This almost instantaneous disappearance of a body of ice more than a foot in thickness can only take place in perfectly still weather. If there is any wind it breaks up, and the fragments are driven up against the ice which still holds together, and into the shores, where the rapidity with which it melts is not so striking. I never was fortunate enough to be actually in at the death.

"There are also some curious facts connected with the air-holes which form themselves during winter. There are often particular spots where partial openings in the ice will be formed every winter. These I conceive to arise from warm springs, and to have no connection with air-holes properly so called, which are not confined to any particular locality, but may appear anywhere. There is always a good deal of air under ice, and you may often see it scattered about in small bubbles when the ice is thin. It is probably air excluded in the process of crystallisation, and when there is added to it sundry gases formed from decaying matter in the water, it amounts during the winter to a considerable quantity. Such collections of air, like the bubble in a spirit-level, are in a very uneasy condition, and are rapidly transferred from one place to another on any casual disturbance of the level, giving rise to one of the numerous noises which are always more or less heard on a lake covered with ice—at least, we used always to attribute to this cause a peculiar groaning sound which was very common. Now, if there should be any casual inequality in the lower surface of the ice, the air will naturally collect there, and if it is above 32° F, which in so far as it consists of evolved gas it probably will be, the receptacle will be increased by thawing. A dome-shaped cavity will thus be gradually formed, which will finally reach the surface; air will escape from below, and the surface-water, of which there is almost always more or less after the snow has fallen, will run down from above, wearing the little jagged channels which are characteristic of air-holes. The whole thing will then after a while freeze up again, leaving an indication of where the air-hole has been in the different colour of the freshly-formed ice. I have tried several such air-holes with an axe when first formed, and have always found them to lead to such a dome-shaped cavity. I remember on one occasion an otter frequenting a large air-hole which remained open for some time, and which must have been from a mile and a half to two miles distant from the nearest open water. How did he reach it? for no otter can travel that distance under water without access to air. The Indians say that they will go to greater distances still under the ice, and that they always find air there. It is likely enough that there may be many such dome-shaped cavities, which have not yet reached, and may never reach, the surface as air-holes, but one would imagine the air they contain to be not of the most wholesome character. However, this otter did frequent that air-hole for about a week, which it certainly did not reach by travelling on the ice, and though it had few chances of breathing there, in the daytime at any rate, it contrived during that period to elude the snares of a white man and an Indian, who wasted a good deal of time in looking after it.

So far, the process of the formation of air-holes, if I am right in my explanation, is intelligible enough; but sometimes they are formed in a manner which is difficult to account for. Upon one occasion I had crossed the lake to a friend's house, about four miles off, and we had determined to start together next morning to our nearest town, but I had to go home first. I first went over by daylight, when there certainly was nothing unusual in the appearance of the ice, which might be four or five inches thick at the time, with a slight sprinkling of wettish snow on it. I returned home about eleven at night, and, as it was bright starlight, with only a few floating clouds, I should have noticed any change; but I came straight across, and saw nothing to attract attention. But when I crossed again at daylight in the morning, in one part of the lake the whole surface was covered with air-holes—there must have been hundreds of them. At first I gave them rather a wide berth, but, on approaching one to examine it, I found it frozen up again, the clear ice in the hole, with very slight indications of the characteristic jagged edges, being the only sign that there had been an open air-hole there during the night. I had no axe with me to try whether they were connected with any cavity, but the appearance was as if holes of from two to five or six inches in diameter had been punched through the ice. Of course, we attributed it to electricity, as people will do anything which they do not otherwise understand, and I have never been able to give any more intelligible explanation of the phenomenon. There certainly had been some faint sheet lightning that night, a very unusual thing in winter; but what connection, if any, there may have been between the two things, I cannot tell.

"Ottawa, Sept. 15" "JOHN LANGTON

The Difficulties of Natural Selection

I FIND, on looking again at Mr. Bennett's article, that I have misrepresented him on one point, for which I beg to apologise. On his supposition, that the first twenty possible steps on the road to mimicry are absolutely useless, his argument will have some weight. This supposition, however, is entirely unsupported by facts. Very large variations of colour are exceedingly common in butterflies; and when such variations are in the right direction, they must in some cases be useful. I believe myself that far less than fifty, or even twenty, steps of variation would in some cases produce very good mimicry.

ALFRED R. WALLACE

Cave-paintings by Bushmen

MY friend, Mr. George W. Stow, of Queenstown, South Africa, refers in a letter to the interesting subject of the old cave-paintings by the Bushmen, as follows: "During the last three years I have been making pilgrimages to the various old Bushman caves among the mountains in this part of the colony and Kaffraria; and, as their paintings are becoming obliterated very fast, it struck me that it would be well to make copies of them before these interesting relics of an almost extinct race are entirely destroyed. This gave rise to an idea in my mind of collecting materials enough to compile a history of the manners and customs of the Bushmen, as depicted by themselves. I have, fortunately, been able to procure many fac-simile copies of hunting scenes, dances, fightings, &c., showing the modes of warfare, the chase, weapons, disguises, &c. This promises to be a collection of very great interest. In some places it is astonishing to what a degree of perfection some of the wild artists had arrived. I have found three different series of paintings, one over the other; and, as the most recent must be upwards of fifty years old, the undermost are most probably very ancient. The colours are very permanent, and would last for ages if not wantonly obliterated. Unfortunately, the Kaffir herds and others are constantly destroying them, and, by the time another generation has passed, few remains of them will be left."

The pigments used in the caves were derived from ochreous concretions abounding in some of the sandstones of the Karoo series of the interior of South Africa, as in the Rhenosterberg, Stormberg, and elsewhere. These concretions, when broken open, supplied the natives with paint-pots, and from among the several colours of yellows, browns, reds, &c., the chocolate was selected for painting the human form in the caves.

T. RUPERT JONES

5, Terrace, Yorktown, Surrey

A Rare Fish

A SPECIMEN of the Silvery Hair-tail (*Trichiurus lepturus*) was taken this morning at Seaton. It measures 2 feet 2 inches in length, and is in very good preservation, being only slightly injured on one side of the head. A specimen from the Collection of the late Mr. F. W. L. Ross, in this museum, is about the same size, and was taken on 6th August, 1852, off the Start Point, Devon. The recorded instances in which this remarkable fish has occurred on the British coasts are very few, and the specimens obtained have generally been much injured. The present specimen was brought to me to name by Mr. Frank Gosden, of the West of England Fish and Game Company, Queen Street, Exeter.

W. S. M. D'URBAN, Curator

Devon and Exeter Albert Memorial Museum,
Queen Street, Exeter, December 3

The Ceratodus Forsteri

I AM much obliged to Dr. Sclater for his remarks on the new fish discovered by me as *Ceratodus forsteri*, and I take this opportunity to inform your readers who may feel interested in this matter, that I spoke of the animal as an amphibian, principally because it is in the habit of leaving the water during the night. The works to which Dr. Sclater refers me are not at my command, and I adopted the generic term of *Ceratodus* because the bulk of my specimens greatly resemble those of the above fossil genus. Professor Agassiz has written to me to say that the discovery of the *Ceratodus forsteri* is of the greatest importance, and that he (Prof. Agassiz) is "amazed" at it. By this mail two of these interesting strangers (with intestines) will be shipped to England, as a present from Prof. A. M. Thomson to Prof. Owen, another by Mr. Ramsay to Dr. Sclater. I am glad to see that my friend Ramsay has complied with Dr. Sclater's request, and ceased classing the *Ceratodus* as "Salmon," which he confesses to have done frequently before. Mr. George Masters, the assistant curator of the Museum, is now at Gayndah, with appliances to catch the fish, and he will, if possible, send some alive to Sydney and to the Zoological Society of London.

Sydney, Sept. 7 GERARD KREFFT

The British Museum Collections

As it is proposed to remove the Natural History collections from the British Museum to Kensington, I hope care will be taken to make the collections as serviceable as possible to students. In particular the British Department might, with great gain to all, be extended and improved. There is now but one small room devoted to British zoology, and this interesting branch of science is poorly represented by a selection of species not always well chosen nor even strictly indigenous. Still, imperfect as it is, I believe this is the only attempt to present a comprehensive view of the British fauna in London. In the new buildings it is much to be desired that a large and well-lighted gallery should be devoted to the zoology of the British Islands, and as complete a collection as possible exhibited. The specimens should be labelled with local as well as scientific names, and, when desirable, short interesting particulars might be given, as on the labels of the art collection at South Kensington. I think no part of the museum would be so well frequented or so generally appreciated by the public. When the labour of removing the collections is over, I hope we may be furnished with catalogues of different departments, with notes of the time and mode of acquisition, &c., of the most important specimens. If begun for the British collections, it might afterwards be extended to the rest of the museum. The nation, which possesses such truly choice and extensive collections, ought to take care that the advantages to be reaped from them are fully developed and placed within the reach of all. A. W. L.

Glass Floats off the Isle of Lewis

THE glass globes to which you refer as having been found on the shores of Lewis, are no doubt fishing floats. The Bergen fishermen have recently begun to use such balls as floats for their nets, and they are occasionally picked up in the North Sea. Those which have been brought to this office were empty, *i.e*, contained no liquid, and bore no distinguishing mark at all. They were picked up about 100 miles S.W. of the Loffoden Islands.

116, Victoria Street, London, S.W. ROBERT H. SCOTT

P.S.—If any of the globes are sent to me, I shall be happy to inquire in Norway about them, and return them, after inspection, to their owners.

The Milky Way

YOUR correspondent, Mr. Jeremiah, after quoting the words of the Llangadock "Oracle," adds, "meaning that the wind will blow from that quarter." Did Mr. Jeremiah interpret the man's meaning correctly? If so it is at variance with a popular belief in Hampshire, *viz.*, that in whichever way the Milky Way may be seen over night, the wind is sure to blow *across* it, or at right angles to it on the following day. HENRY REEKS

The Cockroach

IN some ships infested with these insects, sailors frequently complain of having their toe and finger nails, and the hard parts of the soles of the feet and palms of the hands, nibbled by them. The men have exhibited to me their nails and skin, which had the appearance of having been attacked. I can vouch for the following, as I was the unhappy subject of it. On returning from a shooting excursion in salt swamps in tropical Australia, with my feet blistered and sodden, I was put to sleep in a room swarming with cockroaches (the small species). The night was intensely hot, and my feet were exposed. I had slept soundly for some hours, when an intolerable itching and irritation about my feet awoke me. I felt these objectionable insects running over and gnawing at my feet. On striking a light, I found they had attacked the skin, and entirely eaten it away from a large blister, leaving a raw place as large as a shilling. I slept again, and in the morning found they had completed the work, and established a painful sore. The whole of the hard skin on the heel was also eaten down to the pink flesh. The nails were not attacked. I have now, at a distance of four years' time, bluish scars on the skin

Mill Hill, Nov. 11 ARTHUR NICOLS

I HAVE to thank the Rev. W. Houghton for his references on this subject, and to explain that I wrote Aristotle inadvertently for Aristophanes. My only objection to adopting σίλφη as the Greek equivalent for our cockroach is that the unpleasant smell which is mentioned as a characteristic of the former, is not particularly marked in the latter. If we adopt the view that the cockroach was known to the ancients, we must, of course, reject Gilbert White's story of its American origin, and, as he thought, its recent introduction into England. C. J. R.

KAIETEUR WATERFALL, DEMERARA

THE great Kaieteur Fall, recently discovered by Mr. Brown, has a clear descent, according to barometrical observations, taken simultaneously by Mr. Brown at the bottom, and by Mr. Mitchell, at the top, of 750 feet. Above, the Potaro glides smoothly in a slight depression of the table of conglomerate sandstone, and disappears over the edge in a body, which is estimated at eighty yards in width, and of depth uncertain in the centre, but shallowing rapidly towards either bank. When the Fall was discovered in April, the rocky channel was completely covered, and the stream must have had a width of, at least, 100 yards. During the summer it is diminishing in volume, and, as the Indians state that it will continue to do so till October, only the central and deeper portion, about one-third of the whole, will then remain. The best time, therefore, for a visit is in spring, at the end of what appears to be the rainy season of this elevated tract.

As the Fall was seen by the exploring party who discovered it, nothing can be imagined more beautiful. The central portion, which is never dry, forms a small horse-shoe, or re-entering angle, and the water in this part preserves its consistency for a short distance from the edge. But everywhere else, and here also at a few feet from the top, all semblance of water disappears; it breaks up, or blossoms, into fine foam or spray, which descends in the well-known rocket-like forms of the Staubbach and similar waterfalls, but multiplied a thousand times, into a small dark pool, over a semicircular curtain. The cavern behind the Fall is the home of thousands of swallows, which issue from it in the morning, and may be seen returning in their multitude at night. The Fall itself is one vast descending column of a fine, dry-looking, snow-white substance, bearing a resemblance in colour and consistency to the snow of an avalanche, but surpassing all avalanches in size and in the beauty of the forms taken by the material as it falls. Rainbows of great splendour were observed, one from the front of the Fall in the morning, one from the summit in the afternoon; but this last reverted, forming a coloured loop or ring, into which the whole mass seemed to precipitate itself, and disappear and dart out underneath, black and foaming at the gorge and outlet of the pool.

Eleven days were spent in ascending the Essequibo, which was heavy in flood, and detained the party double the time anticipated; five days brought them from Tomatomari, the lowest fall on the Potaro, to the Patamona village. In this stage there are five cataracts, two of which, at least, are inaccessible. Two days were occupied in visiting the foot and summit of the Fall, and in descending to the Settlement, leaving Messrs. Brown and King to complete the survey and sketches of the country in four days and a half.

QUERIES RESPECTING ÆTHER

THE following speculations first appeared in the pages of the *Engineer*:—

When light and caloric were supposed to have a material existence, the hypothesis of the universal existence of a highly elastic medium was unnecessary, since matter might with the utmost freedom be projected through vacuous space; but as light and heat are now generally admitted to consist not of transmitted matter, but of transmitted vibratory motion (and why may not electricity, so freely interchangeable with the former, be admitted into the same category?), the necessity of the existence of a transmitting medium, pervading infinite space, becomes at once apparent; and this medium, hitherto not cognisable to our senses, has been termed æther.

But it has been further assumed that æther is alone capable of transmitting the extremely rapid vibration of light and heat, and that it must therefore necessarily pervade or permeate all kinds of sensible matter. The questions proposed to be raised in this communication are the necessity of this interstitial hypothesis, and the probable capability of ordinary matter to transmit the vibrations of light and heat.

It is now generally admitted that when a body becomes heated, its own particles, and not those of the supposed interstitial æther, are thrown into a state of vibratory motion, the amount of heat corresponding probably to the amplitude of the vibrations; hence a certain amount of energy has been communicated to those particles, and, at all events, in the case of celestial mediations, the molecules of æther must previously have possessed the energy or *vis viva* which they have communicated. Hence æther, being susceptible of *vis viva*, has recently been admitted to be ponderable, but this admission is not a necessary consequence, for although the idea of the existing energy is associated with that of weight, in consequence of the constant energy acquired by gravitation having been taken as the measure or unit of energy, however acquired, there is no necessary connection between them. Suppose, for example, a flea were placed on an orbilating planet of the size of a pumpkin, while its muscular energy would remain undiminished, its weight would be infinitesimal, and the first leap would obviously plunge it into infinite space, to perform subsequently, perhaps, an independent orbit.

Further, it has been shown from the investigations of Mr. Norman Lockyer, to whom the progress of solar physics is so largely indebted, that incandescent gases are capable of initiating vibrations of definite periods, which are, moreover, occasionally accelerated or retarded by the proper motion of the emitting gas. What reason can there then be for doubting that gaseous matter is capable of transmitting heat waves, and if so, of likewise transmitting the waves of light, since the two are so intimately connected by the identical phenomena of reflection, refraction, and polarisation? May not in fact, in some instances, the perceptions of light and heat be but different sensuous impressions produced by the same vibrations?

The only basis on which the interstitial-æther hypothesis rests is the assumed incapacity of ordinary matter, whether in the solid, liquid, or gaseous state, to transmit the vibrations of light and heat, because the only vibrations, namely, sonorous, with which we are acquainted, are almost immeasurably slower than those of light and heat, the one being numbered by at most a few thousands, the other by hundreds of millions of millions in one second of time.

But it must be borne in mind that sonorous vibrations are always longitudinal, in the production of which repulsive forces are alone concerned; whilst, on the contrary, light and heat vibrations are necessarily transverse, and the production of these is solely due to attractive forces. Now these respective forces obey very different laws, for whilst attractive forces obey generally, and probably universally, the laws of the inverse square of the distance, molecular repulsion must obviously, at all events in gaseous matter, obey the laws of the inverse cube of the distance; therefore, from the rate of transmission of longitudinal vibrations, nothing can be predicted respecting the rate of transmission of transverse waves. It has been asserted that molecular repulsion is a dynamical resultant effect, and, therefore, incapable of expression by a statical law; but it is very doubtful whether molecular attraction is not equally a dynamical sequence, and, therefore, not a whit more entitled to claim a statical law than the former. Now, in the denser forms of matter, namely, the solid and liquid, it appears that the wave-lengths of created transverse vibrations are indefinitely modified, probably by the more energetic action of repulsive forces; for whilst any given kind of matter in the solid or fluid state is found, when incandescent, to emit light and heat waves of all lengths, and so to form a continuous spectrum, the same matter in the form of incandescent gas will emit only a few sets of waves of definite and invariable lengths; and, moreover, some of these wave-lengths are frequently found to bear very simple numerical ratios to each other. And even in gaseous matter it has been observed that the bright lines in the spectrum become narrower and more sharply defined by rarefaction; and, on the contrary, broader and less defined by condensation. Moreover, as regards density, the absorption bands in the spectrum appear to obey the same law as the bright lines. In other words, every kind of matter appears to be capable of emitting or absorbing its own peculiar waves, according to its tenacity; that is, as the results of molecular attraction are less and less interfered with by those of repulsion. The well-known peculiar incapacity of any given translucent substance to transmit the heat rays emitted by a heated portion of the same substance; or, in other words, the ability of the molecules to freely appropriate the wave motion that has been induced by some intervening medium by similar molecules, seems further to argue that ordinary matter is capable of assuming vibrations having the extreme rapidity of those of light and heat. And that there exists no valid ground for a distinction between light and heat in this respect is further confirmed by the experiments of Prof. B. Stewart, who has shown that the emission of light by incandescent bodies closely corresponds with their absorptive power (whether selective or otherwise) when not incandescent; and, further, that even in the decomposition of light into true polarised beams by the tourmaline it emits, when incandescent, the ray that is otherwise absorbed.

Can there, then, be any valid reason for doubting the ability of ordinary matter to transmit those transverse vibrations, which it is obviously capable of either absorbing or emitting: and if so, what ground is there for the hypothesis that the transmission of light and heat waves necessitates the presence of imperceptible æther in the interstices of perceptible matter?

If the existence of æther in infinite space, essential to the undulatory theory, be admitted, it may be asked, how is it possible to conceive its exclusion from any portion of space? A very simple hypothesis propounded by the writer in the introduction to the last edition of his "Elements of Physics" will meet this difficulty, namely, that æther (like its fluid namesake with water) is *immiscible* with known gaseous matter. This, it must be admitted, is sheer hypothesis; but if true, it must ever remain so, as being beyond the reach of human ken. But of this we may rest assured, that if it be not wanted in and around even our corporeal frames, it is not there; the contrary supposition would be inconsistent with the infinite wisdom of the Creator of the universe.

CHARLES BROOKE

SPECTROSCOPIC NOTES *

A NEW FORM OF SPECTROSCOPE

THE instrument, a description of which follows, was designed for attachment to the equatorial of 6·4in. aperture and 9ft. focal length, belonging to the observatory of Dartmouth College. It is especially intended for observations upon the solar spots and protuberances, and accordingly the principal object kept in view has been to combine a very high degree of power with compactness, lightness, facility of manipulation, and firmness of construction. Having the dispersive power of 13 prisms of heavy flint, each with an angle of 55°, it yet weighs less than 15lb., and measures over all 15in. in length, 8in. in breadth, and 4½in. in height. It was make by Alvan Clark and Sons.

The accompanying plate (Fig. 1), taken from a photograph, gives a correct idea of its appearance and general arrangement. The collimator and observing telescope have each an aperture of ⅞ths of an inch, and a focal length of 7in., which might advantageously have been increased to 12in. were it not for the necessity of compactness.

The light from the slit, after passing the collimator, is transmitted through the lower portion of a train of six prisms of heavy flint glass each 2¼in. high, and having, as stated above, a refracting angle of 55°. A seventh *half-prism* follows, and to the back of this is cemented a right-angled prism, by which, after two total reflections, the light is sent back through the upper part of the same train of prisms, until it reaches the observing-telescope. This is placed directly above the collimator, and firmly attached to it. Finally, a diagonal eye-piece brings the rays to the eye in a convenient position for observation.

The instrument has thus the dispersive power of thirteen prisms, and even with the low magnifying power of only five on the observing telescope, shows perfectly the lines of aqueous vapour, which make their appearance between the sodium lines when the sun is near the horizon. Of course, everything shown on the maps of Kirchhoff and Angström is readily seen with it, and many lines besides.

Its definition is very beautiful, and the only optical fault of the instrument seems to be a curvature of the lines, resulting from the shortness of the collimator.

After planning the instrument, I learned that the same idea of sending the light twice through the prisms by a right-angled

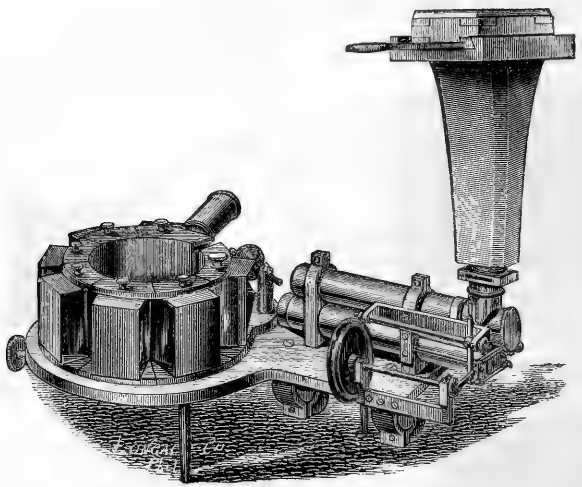


FIG. 1.—A NEW FORM OF SPECTROSCOPE

prism at the end of the train had also occurred to Mr. Lockyer and others; but I do not know that it has yet been put in practice elsewhere.†

The prisms, for protection and convenience of handling, are set in frames of blackened brass. They are arranged around the circumference of a hollow cylinder of elastic gun metal, 3½in. in diameter, with stout flanges above and below, between which they are clamped by little thumb-screws, so that they can be readily removed or transposed: it requires less than a minute to put the last prism with its reflector in place of any other of the train, thus reducing the dispersive power to any extent desired.

No particular care is required in placing the prisms, as a couple of narrow flanges were cast upon the cylinder near the top and bottom, and afterwards planed off to form true bearings for the backs of the prisms. They are thus always correctly set by being simply slid home before tightening the clamping screws.

The lower flange of the cylinder is attached to the base-plate by a screw directly under the middle of the front face of the first prism. Around this point as a centre the whole system of prisms is movable by means of a double-threaded tangent-screw, which brings the different portions of the spectrum into the field of view. The adjustment of the prisms to their angle of minimum deviation is effected by a method devised by Mr. George Clark, which is exceedingly simple, and, if not theoretically exact, answers every practical purpose. The flanges between which the prisms are clamped, are sawed through between the prisms, and a portion of the cylinder, flanges and all, equal to an arc of about 30°, is cut out between the first prism and the last. On closing up or spreading open this gap by means of a suitable tangent-screw, the circumference of the circle around which the prisms stand is correspondingly enlarged or diminished. Probably, when the ends of this opening are drawn very near together, or spread very far apart, the cylinder is somewhat distorted, and a corresponding mal-adjustment of the prisms results; but if so the effect is very slight.

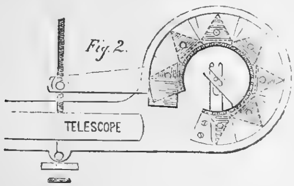
The instrument gives a perfect view of every part of the spectrum from below A to H: above *h*, however, when all seven prisms are used, there is a loss of light occasioned by a partial obstruction of the apertures of the collimator and telescope by the corner of the reflecting prism.

* From the Journal of the Franklin Institute.

† An instrument exactly similar in all essentials to the one here described has been used by Mr. Lockyer for more than a year past.

Were it important to secure the perfect cylindricity of the prism-frame through the whole range of adjustment, it could be easily done by merely fastening at the back of each prism a radial bar acting upon a central pin, as in the arrangement first devised by Mr. Rutherfurd, and since adopted by Mr. Browning, in his automatic spectroscope.

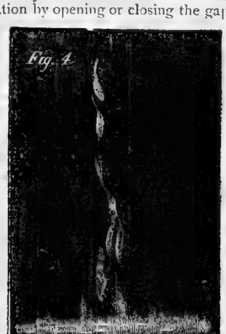
This plan of Mr. Clark's, doing away with all joints and hinges, has the great advantage of perfect firmness and solidity in every



position of the instrument, an advantage hardly to be overrated in an astronomical spectroscope.

Had it occurred to me in season I might have made the instrument still simpler, firmer, and perfectly automatic in its adjustment, by merely substituting for the first prism a half-prism,* like the last of the train, to which the right-angled reflecting prism is cemented.

Placing the first half-prism with its front face perpendicular to the line of collimation, it would never need to be disturbed; the flange of the cylindrical frame which carries the prisms would be firmly fastened to the bed-plate immediately beneath it, and the pivot joint at this place with the corresponding tangent-screw would be dispensed with. The only adjustment required would be that produced by the screw which is now used to adjust for minimum deviation by opening or closing the gap of the cylinder.



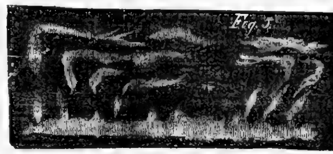
Of course, this arrangement would reduce the dispersive power of the train by the amount of one prism, a loss easily made up by adding a degree or two to their refracting angles.

Fig. 2 exhibits the plan of the proposed arrangement, and requires no explanation, unless to remark that for the sake of distinctness I have represented only two of the radial bars which may be used to render the adjustment accurate.

* On returning from the Eclipse Expedition my instrument will be made automatic in accordance with this plan.

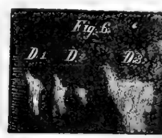
It might be better to place the face of the first prism not exactly normal to the line of collimation, in order to avoid repeated reflections between it and the object-glass of the collimator, which would be likely to produce a troublesome ghost, or the same thing might be accomplished by simply cementing the object-glasses of both collimator and observing telescope directly upon the front of the prism; this would make the instrument still more solid and compact.

The eye-piece of the instrument has an apparatus attached, which, however, thanks to the high dispersive power, I find unnecessary.



It was early proposed by Janssen to use a vibrating or rotating slit in order to make visible the form of a solar prominence, but as Zöllner has shown, the mere opening of the slit answers just as well, the light of the protuberance being diluted to precisely the same extent in either case.

It occurred to me in connection with a suggestion of Professor Morton, that by interposing at the focus of the eye-piece a diaphragm which should move with the vibrating slit, the light of the neighbouring portions of the spectrum might be cut off and this dilution avoided. Mr. Clark has devised and constructed a very beautiful mechanical arrangement by which this simultaneous and accordant motion of slit and diaphragm is effected by the rotation of the small fly-wheel shown in Fig. 1.



But I find, that although seen in this way, the prominences appear very bright; yet the working of the apparatus always causes a slight oscillation of the equatorial, which interferes with the definition of details, and I prefer to work with the slit simply opened. When the air is free from haze, the whole extent of a prominence 30,000 miles in height is readily examined through the C or F line, and the most delicate details reveal themselves with a beauty and clearness of definition which even yet always surprises me, and speaks most emphatically for the exquisite workmanship of the 43 different surfaces by which the light is either refracted or reflected on its way from the slit of the collimator to the eye.

But, although I do not use the vibration of the slit and diaphragm, I find the mobility of the slit so convenient as to be practically indispensable. In examining the spectrum of a group of sun-spots, for instance, it is very much easier to move the slit to the particular point we wish to observe, than to move the solar image by the tangent screws of the equatorial.

Photographs of the Solar Protuberances

The protuberances are so well seen through the F and 2796 (near G) lines, that it is even possible to photograph them, though perhaps not so satisfactorily with so small a telescope as the one at my command. Some experiments I have recently made show that the time of exposure, with ordinary portrait collodion, must be nearly four minutes, in order to produce images of a size which would correspond to a picture of the solar disc about 2 in. in diameter. This length of exposure demands a more perfect clockwork than my instrument possesses, and a more accurate adjustment of the polar axis than it had during the experiments, as well as a steadier condition of the atmosphere.

Thus far, therefore, I have not been able to produce anything which could properly be called a good picture. Negatives have been made which show clearly the presence and general form of protuberances, but the definition of details is unsatisfactory. This amount of success was reached upon September 28, when impressions were obtained of two protuberances on the S.E. limb of the sun, and, slight as this success was in itself, I consider it of importance in showing the perfect feasibility of going much further with more sensitive chemicals, more delicate adjustments, and greater telescopic power. I was aided in the experiments by Mr. H. O. Bly, our local photographer, to whom are due my warmest acknowledgments for the interest, patience, ingenuity, and skill with which he assisted me.

We worked through the Hydrogen γ line (2796 of Kirchhoff's scale) which, though very faint to the eye, was found to be decidedly superior to F in actinic power. The photographic apparatus employed consisted merely of a wooden tube, about 6 in. long, attached at one end to the eye-piece of the spectroscope, and at the other carrying a light frame. In this frame was placed a small plate-holder, containing for a sensitive-plate an ordinary microscope slide, 3 in. by 1. The image of the prominence seen through the open slit, is magnified and thrown upon this plate by the eye-piece. Fig. 1 shows the instrument with this apparatus attached.

It would be easy to improve this arrangement in many respects, and whenever I resume the subject I propose to do so.

As the equatorial, however, has been dismounted, to be put in order for the observation of the December eclipse, further attempts in this direction must be postponed until next spring.

Observations of the Solar Protuberances

Without prolonging this article with the detail of observations, I add a few of the results which have been obtained since Sept. 10.

About forty different prominences have been more or less carefully observed; sixteen have been sketched. Most of them fall, naturally enough, into the categories established by Zöllner and Lockyer, and are fairly represented by figures already published in the *Journal of the Franklin Institute.*

A few deserve especial mention, however. Fig. 3 represents a small one which was observed upon the E. limb of the sun, on September 14, about 4.30 P.M. From the point marked A, which was very brilliant, a small fragment detached itself and rose towards A′, enlarging in size and growing fainter as it rose. It disappeared (from faintness) in about $12\frac{1}{2}$ minutes, at a distance of 2′ 30″ above the limb of the sun, as determined by the time, 8″·5, which was occupied by the intervening space in passing over the slit of the spectroscope. Allowing for the obliquity of the motion to the parallel of declination, the length of path passed over by this cloud was more than 90,000 miles, and the velocity above 120 miles per second.

Fig. 4 represents a prominence observed September 20, at 4 P.M., on the S.E. limb. (Pos. S., 60° E.) It was a nearly vertical stream, made up of spindle-formed filaments, and had attained the enormous height of 3′ 20″ or 90,000 miles (determined, as in the case above mentioned, by a time-observation, corrected for inclination). It was very brilliant near the base, and at two or three other points along its length. At 4.30 it was nearly gone, only a few faint wisps of cloud remaining.

Another, observed on September 27, at 4.10 P.M., and situated on the W. limb of the sun, is represented in Fig. 5. It was formed of separate, well-defined narrow streamers, which appeared to consist of matter, first violently ejected, and then as violently deflected, by some force acting nearly at right angles. The altitude of the highest point was 1′ 25″, the length of the whole about 3′ 30″. I am unable to see how any mere projection from the sun could have produced such a form, and cannot help feeling that it indicates a something in which powerful currents may exist, even at great elevations above the solar surface; in short, an atmosphere extending far beyond the limits which calculation would seem to assign as possible. Is it wholly unlikely that at such an enormous temperature the law of Mariotte may fail so completely as to destroy the reliability of any computation that assumes it as one of the data?

Upon the next day the prominence still persisted, but its type was wholly changed: it was replaced by one of the mushroom-formed masses which are so common.

Bright Lines

In the spectra of different protuberances, the following bright lines have been observed, the numbers referring to Kirchhoff's scale: C; D_1; D_2; D_3; 1474; 1515; b_1; b_2; b_3; b_4; 1990; 2001; 2031; F; 2581·5; 2796; h—17 in all. On one occasion, September 27, the base of a prominence on the N.W. limb, close to a spot just leaving the limb, exhibited as many as twelve or fifteen short bright lines between E and F, which are not included in the above enumeration, as I had not time to identify them. It is the only instance in which I have seen this phenomenon, more than once described by Mr. Lockyer.

I desire to call special attention to 2581·5, the only one of my list, by the way, which is not given on Mr. Lockyer's. This line, which was conspicuous at the eclipse of 1869, seems to be *always present* in the spectrum of the chromosphere, and shows the form of its upper surface or of a protuberance nearly as well, though of course not so brightly, as the 2796 line. It has no corresponding dark line in the ordinary solar spectrum, and not improbably may be due to the same substance that produces D_3.

The reversal of the sodium and magnesium lines is not at all uncommon. In some instances these lines were so bright that on opening the slit the form of the prominence could be made out through them. This was the case with a small hand-shaped prominence observed on September 27. Comparing the form thus seen through D′ and D_2 with that given by D_3, it appeared that the sodium line was sufficiently developed for observation only along the edge and at one or two bright points in the prominence, most brilliantly neither at its summit nor its base. Fig. 6 represents the appearance (the slit was perpendicular to the sun's limb). The case was similar with the magnesium lines.

Spectrum of Solar Spots

Several spots have been carefully examined at different times; most of them, in their spectra, gave evidence of unusual disturbances; but by far the most interesting phenomena were exhibited by a large group which was first observed near the E. limb on September 19. Changes of wave-length were frequent in its neighbourhood.

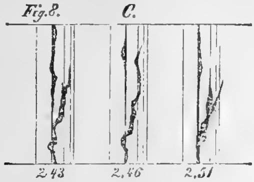
Figs. 7 and 8 represent the appearances assumed by the F and C lines respectively, at the times indicated below each figure, during an observation on the afternoon of September 22. The point where these changes of wave-length occurred was at the western edge of the penumbra. At other times similar changes were observed, but not so great or rapidly varying.

The calcium and titanium lines referred to in my note published in the July number of the *Journal of the Franklin Institute,* were always conspicously thickened in the nucleus spectrum.

The C and F lines were reversed in some portion or other of the group nearly every time I observed it. On September 22 the sodium lines were both reversed for several hours, while D_3 appeared as a dark shade. On September 28, again, at 4 P.M., the southern nucleus of the group (which at this time contained four large umbræ, besides many small ones) reversed all of the following lines, viz.: C; D_1; D_2; D_3; 1474; b^1; b_2; b_3; b_4; F; 2796, and h. All of these were conspicuous, except 1474; D_3 and b_3 especially so, and the latter (a nickel line) showed considerable changes of wave-length, alternate increase and diminution, which were not shared by its magnesian neighbours, b^1, b_2 and b_4.

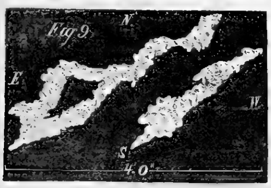
At 4·05 P.M. the brilliance of the F line increased so greatly that it occurred to me to widen the slit, and to my great delight I saw upon the disc of the sun itself a brilliant cloud in all its structure and detail identical with the protuberances around the limb. Indeed, there were *two* of them, and there was no difficulty in tracing out and delineating their form. Fig. 9 represents them as they were from 4·05 to 4·10; Fig. 10 gives the form at 4·15 to 4·20. They were then considerably fainter than at first. During the intervening ten minutes I examined the other lines of the spectrum, and found that the form could be distinctly made out in all the *hydrogen* lines even in h; but that the reversal of the other lines, including D_3, was confined to the region immediately over the spot-nucleus, where the smaller but brighter cloud terminated abruptly; or, I might better say, *originated.* The larger one faded out at both ends. When the clock-w--

of the equatorial was stopped, the luminous cloud took 16·7 seconds of time to traverse the slit which was placed parallel to the hour-circle. This indicates a length of at least 130,000 miles without allowing anything for the foreshortening resulting from the nearness of the sun's limb.



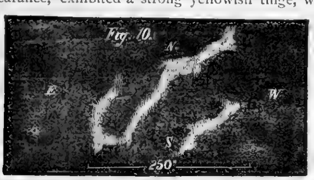
By five o'clock the clouds had nearly disappeared; a little rack alone remained.

At 4.20 I examined the spot with the equatorial, using the ordinary solar eye-piece. Nothing remarkable was to be seen—not the merest trace of the enormous masses of incandescent gas.



It will be interesting to learn whether the earth responded to this magnificent eruption on the sun by any magnetic storm.

I may add that in the telescope this group of spots, from their first appearance, exhibited a strong yellowish tinge, which ap-



peared to overlie all the central portion of the cluster. So conspicuous was it that several persons, unaccustomed to astronomical observation, noticed it at once before I called their attention to it. The penumbra of the group was unusually faint.

Hanover, N.H., October 3 C. A. YOUNG

NOTES

THE first detachment of the Eclipse Expedition for Spain and Algiers started from Portsmouth in H.M.S. *Urgent* on Tuesday morning; the Sicilian party followed overland yesterday evening. An error crept into the names of the party in our list published last week. Professor Roscoe's assistant is Mr. Edward Ernest Bowen, M.A., late Fellow of Trinity College, Cambridge.

AT one of the most recent sittings of the French Institute a communication was made by M. Faye on the intended departure of M. Janssen to join the Eclipse Expedition. This celebrated astronomer was to leave Paris in a balloon constructed for his private use at the expense of the French Government, and which will also carry a telescope, constructed in eight weeks by the most skilful workmen in Paris, and of the capacity of 2,000 cubic metres. It will be fitted up with a new kind of valve, invented by M. de Fonvielle, and which was not quite ready when that gentleman left Paris. According to every probability M. Janssen will ascend with M. Tournier, one of the passengers in the "Pole Nord," but taking the management of the balloon under his own care. The telescope was put in hand a very few days after the 4th of September. The Government appeared so anxious to show the interest taken in the matter that they did not lose a single day after they came into power in fitting up this expedition. The expenses of the construction of the telescope were incurred by the Bureau des Longitudes.

THE French *Académie des Sciences* has held its sittings regularly since the commencement of the siege, and the *Comptes rendus* has been published regularly every week. Every sitting is reported fully, and several numbers have had even more than the average number of pages. A large part of them is devoted to military science and to ballooning. The scheme put forward by M. Dupuy de l'Ome was fully discussed and illustrated by copper-plates: an article contributed to the *Presse*, by Mr. Giffard, the celebrated engineer, when reporting upon his aërial experiments as much as twenty years ago, has been reprinted. It was shown that Dupuy de l'Ome's experiment was almost of the same nature, and the *Académie des Sciences* has apologised for not publishing it in proper time. M. Dumas and M. Elie de Beaumont, although members of the former senate, now act in their capacity of *sécrétaires perpetuels* of the Academy. M. Leverrier has not appeared at any of the sittings. M. Chasles is most punctual in his attendance. Lectures are given at the *Conservatoire des Arts et Métiers*, and are to be given at the *Collége de France*. No lectures have been given this session at the *Sorbonne*. Since the commencement of the siege, a few numbers only have been issued of the *Révue des Cours Scientifiques; Les Mondes* and *Cosmos* have been entirely suspended.

A LARGE number of the animals at the *Jardin des Plantes* and *Jardin d'Acclimatation* have been sold and slaughtered for food, even the bears having now been sacrificed. The trees in the latter garden have been almost entirely cut down either for charcoal or for the necessities of the defence.

WE are very glad to be able to report that Sir Roderick Murchison has gained strength during the past week, though his state still continues critical. Prof. Balfour Stewart will have to remain at Harrow for at least some weeks, but is progressing as satisfactorily as possible, considering the nature of his injuries.

THE ratepayers of Marylebone have done good service to Science in electing Miss Garrett, M.D., and Prof. Huxley to the London School Board, first and second on the poll, the former by a triumphant majority over every other candidate. If their example is generally followed throughout the country, we may anticipate great things in the future for the scientific education of the country.

OWING to Professor Tyndall's absence with the Eclipse Expedition, the first conversazione at the London Institution, announced for Dec. 21st, is postponed till Jan. 25th, when he will deliver his lecture on Dust and Disease.

WE regret to learn that the North London Naturalists' Society terminated its existence on Monday, Nov. 27. It has been established for about six years, and was for some time carried on with spirit; but the interest in it has for some time been on the decline, and it was considered advisable to bring it to a close. We understand that it is in contemplation to form another society in its place, which only actual workers will be invited to join. When we consider how many useful bodies of this description are scattered throughout the country, it seems strange that a similar one cannot be kept afloat in London; but the fate of the North London Club, preceded as it was by the collapse of the Society of Amateur Botanists, and of the West End Naturalists'

Society, is somewhat discouraging, and a well-supported body of workers in all branches of Natural Science seems likely to be a desideratum.

PROF. HASSKARL reports that the cultivation of Cinchona in Java is proceeding satisfactorily. The weather, on the whole, has been favourable, and the growth of the plants leaves nothing to be desired. The number of plants grown from seeds and layers is upwards of one and a half millions, by far the greater number belonging to the species *C. calisaya*, a good many to *C. officinalis* and *succirubra*, and a very few to *C. lancifolia* and *micrantha*. In addition to these, 870,000 plants have been transplanted, and the whole shows an increase of nearly 200,000 plants since the commencement of the year. 460 kilogrammes of the dry bark were sent to Holland in December, 1869, and sold at from two to three florins per kil.; 900 kilogrammes have since been exported, and more than 1,000 were ready at the date of the despatch. Prof. Hasskarl reckons the total produce of 1870 at no less than 4,000 kilogrammes of dry bark for exportation, besides some hundreds for home use in the island. An important branch of industry in the colony is now formed by the stripping, cutting, drying, sorting, and packing of the Cinchona.

THE report of the Hartley Institution, Southampton, for the current year gives a very favourable account of its position and prospects. The students in the day classes have increased from twenty-nine last year to eighty-six; in the evening classes there have been thirty-one. Among the students of the engineering department there have been as many as eighteen government nominees to the Telegraphic Service of India, who have been pursuing an advanced course of instruction in mathematics and physical science to qualify them for their final examination. A class of fourteen nominees has also been under instruction in the Institution during the year in practical telegraphy. At the last final examination for appointments to the Indian Telegraphic Service, all the successful candidates, except one, had been instructed in the Institution. There is a library of 400 or 500 volumes in connection with the Institution, a reading-room amply supplied with the current literary, scientific, and political publications of the day, and a good course of lectures was delivered during last session.

A WRITER in the *Boston Post* of October 24 thus describes the present condition of the Museum of Comparative Zoology in that city:—Since the acquisition of the private collection of Prof. Agassiz, the Boston Museum may claim to rank among the foremost institutions of its kind; for although the British Museum in London and the Jardin des Plantes in Paris are on a very much larger scale, yet in certain departments, such as corals and fishes, the Museum of Comparative Zoology is superior to both, while the increase of its collections since its existence, and the prominence it has attained among other museums, are such as no like establishment has reached in the same time and with the same means. From want of room the greater part of the Museum as it now exists is occupied by working-rooms and store-rooms, and only four rooms are devoted to exhibition. Each of these contains the representatives of one great division of the animal kingdom, and it is intended to complete them in such a manner that they shall exhibit in an easy and conspicuous way the natural relations of all the animals known in creation. In the new building now going up, which adjoins the present Museum and is to be of equal dimensions, it is intended to exhibit all the animals peculiar to the different parts of the world, in such a manner as to impress the observer with their natural association in nature, so that the student of Natural History shall be able to make himself familiar in one part of the building with the latest result of scientific research in working out the system which binds together the whole animal kingdom as a unit; while in the other part of the building their geographical distribution upon the whole surface of the earth, and their various combinations and associations on different continents will be made apparent. Such a twofold arrangement of collections has never yet been attempted in any museum, not even in the largest and most prominent institutions of the kind in Europe. The fossil remains of past ages will be exhibited in like manner in such an arrangement as to display at the same time their order of succession in geological periods, and their relations to the animals now living. It is intended to complete this plan by exhibiting also the different stages of all known animals, from their earliest period of development in the egg to their adult condition. This is a truly magnificent plan, but although the addition to the Museum will double the amount of room, yet the whole of this plan cannot be carried out at present, and a large part of the collections must still remain in the store-rooms until another section of the building can be completed. It is sincerely to be hoped that the strong interest which has already been shown by the Legislature of Massachusetts and the citizens of Boston will not flag, and that sufficient aid will be given to carry out and fully complete this admirable work, within the lifetime of the distinguished man who has done so much to elevate the tone of thought, and improve the method of education in this his adopted country.—We imagine it must be only typical animals of each group that are referred to in the above account. It is to the munificence of a private patron of this Museum, Mr. Nathaniel Thayer, that Science is indebted for Prof. Agassiz's recent exploration of Brazil, with six trained assistants.

A SECOND paper on "Mystic Trees and Flowers" appears in *Fraser's Magazine* for this month. Herbaceous plants form the subject of this portion, the mandrake (of the history of which an especially interesting sketch is given), mistletoe, rose, lily, violet, and primrose, being the principal which are touched upon in detail. The author, Mr. Moncure D. Conway, in some concluding remarks, states his belief that "the reverence paid to trees and flowers" must be looked upon "not as fetish worship, but as a sacred regard paid to them as oracles of beings higher than themselves," and combats the idea "that it was from these lower objects that reverence gradually ascended to the adoration of the sun and stars, as the case was really the reverse."

THE *British Medical Journal* quotes the following description of "The Nemesis of Tobacco," from the ninetieth observation of Theodorus Kerckringius, M.D. (*Spicilegium Anatomicum*, Amsterdam, *circa* 1670) describing the *post mortem* appearances of an inveterate smoker:—"Too greatly, now, alas! in Europe, prevails that *cacoëthes* of sucking up the smoke of the herb tobacco, as they call it, through tubes actually manufactured for that special purpose! In consequence, what a perversity of morals has arisen they must have noted whose duty it is to attend to the public morality, whether they be politicians or theologians. How noxious it is to the health of those who indulge in the habit of sacrificing so often to Vulcan, or rather to Charon, I shall not here explain. Let it suffice, that I adduce the case of a man whose body I opened before the Faculty. He, ordinately given to these fuliginous delights, had scarcely ever engaged in any kind of work, as it appeared, without inhaling this fatal juice. When, however, at length, Nature, assailed by frequent attacks, began to fail, and to give way to disease, he rejected for so long a time a black-looking matter, both upwards and downwards (*per utrumque gutturem*) that at last he vomited forth his dusky soul; which to accompany in its visit to the realms of Pluto would be far from agreeable, for, I suspect, it would greatly, and that from habit, have preferred those black lakes, steaming with the bubbles of Stygian vapours, to the lucid stars of heaven, inasmuch as it had long been fed, though not nourished, by smoke; the abode, however, it had relinquished, I visited and examined by the aid of the scalpel of the anatomist. What did I observe, you ask? It appeared to me that I was passing into the very house of Pluto himself; even the entrance-doors were tinged of a black colour, and the tongue, imbued, as it were, with the poisonous juice, was in a state of tumefaction. What as to the windpipe? It was like the inside of a chimney, coated completely with black grime. The lungs were dry, sapless, and scarcely at all friable. The liver, as if it, beyond all the other organs, had attracted the fire, was altogether inflamed; from the flames of this fire not even the bile in its receptacle had been safe, for its colour had changed from purple to green (*ex purpureo virescentem*). In the intestines, however, the drains of the body, the carbonaceous matters from the whole combustion had become concentred, for they were full of a black substance which exhaled no milder stench than that of Hell itself. Such, of this frequent suction, are the medicinal fruits!"

AT the meeting of the Geologists' Association, on Friday evening last, Mr. R. Etheridge read a paper on "The British Islands Past and Present, Physically considered." After making some remarks on the intense interest and importance of the subject, he proceeded to describe the distribution of land and water at different geological epochs, and to show that England, Ireland, and the Continent, were once united, and that the many and great changes which have taken place have arisen from the elevation or depression of the land, not from alteration of the sea level. Mr. Etheridge then referred to the changes which have taken place in the relative positions of land and water during the historic period, giving instances of towns and cities that in the time of their prosperity stood some distance from the sea, but have been gradually submerged, and other places, whose importance arose from their contiguity to the ocean, now left high and dry inland. The paper was illustrated by a splendid collection of diagrams.

THE Seventh Annual Report of the Belfast Naturalists' Club shows that this useful Society is making good progress. By the kindness of the Council of the Natural History Society, members of the Club have been permitted to re-arrange the valuable local collections in the Museum; and a large sum has been granted by the Council for cases, &c., in which to exhibit a complete local collection. The local land, freshwater, and marine shells have been named and arranged; the Herbarium is in progress; and the Geological collection selected and named, ready for mounting. The Committee have also considered it desirable that the Club should prepare complete lists of the fauna, flora, geology, and archæology of Ulster, by publishing an annual contribution to such a work in addition to the ordinary report. The Appendix in the present issue consists of a list of the Irish Liassic Fossils, with notes on new and critical species, by Ralph Tate, Esq., F.G.S. The number of species enumerated is 189; of which the following are new to science:—*Chemnitzia punctata*, *Solarium thompsoni*, *Tornatella robinsoni*, *Pleurotomaria tectaria*, *Hinnites angularis*, *Avicula pattersoni*, *Leda v-scripta*, *L. quenstedti*, *Cucullæa griingeri*, *Mytilus subtulis Thracia æquata*, *Anatina myacina*, *Pollicipes alatus*. Figures of many of these are given in an accompanying plate, and the paper is a valuable contribution to local geology. We congratulate the Belfast Club on having successfully started a work which will give a permanent value to their annual reports, and trust that their example will be widely followed by other local societies.

IN the Chittagong district the Government of India has discontinued explorations for coal at present, as the samples found are of an inferior and unpromising quality.

BALLOON ASCENTS FOR MILITARY PURPOSES

AS soon as the war broke out, balloons, which had been so long forgotten by statesmen, were recalled to their memory by hundreds of projectors. Some of the schemes suggested were of the wildest description; and scientific men took advantage of this circumstance to reject everything connected with aëronautics. But surprises and reverses became so frequent in the French army, that it became evident that any apparatus able to carry observers would be considered as a preserver from such disgraces. As soon as it was clear that the Prussians were intending to besiege Paris, the Minister of War issued orders for the construction of a captive balloon, intended to watch the movements of any besieging army moving round the capital; but instead of having recourse to Mr. Giffard, the constructor of so many magnificent balloons, it was resolved to employ MM. Godard and Nadar. Paris was divided into aërial districts, the first being given to Nadar and the other to Godard. Nadar then received orders to establish his balloon on the foot of Buttes Montmartre, and Godard close to the Montsouris Meteorological Observatory on the banks of the small streamlet Bièvre, where it crosses the fortifications. The balloons intended to be attached were not made on purpose, they merely used old ones which were worn out; the gas-pipes were also not sufficiently large, and the gas-pressure was very low, so that when the first attempts at inflating were made, the Godard balloon took more than three days to be filled; and, when filled, was tossed so heavily by the wind, that it was necessary to let the gas escape. Nadar was still more unfortunate, and could not arrive even at the inflating of his balloon, except after immense labour, by laying a pipe along the ground for a space of more than 300 yards. Moreover, when the first balloon was floated, it was as late as the 4th of September. I then ordered Godard to continue his inflating process. Many scientific bodies met, and deliberated upon the modes of improving captive balloon ascents; but none of the members had ever ascended, and hence their practical knowledge was so small as to amount practically to nothing.

I tried to improve in some respects the construction of captive balloons, by using the process of fixing to the rope invented and practised by the aëronauts of the First Republic, and offered to the State a balloon, which had been given to me by my friend, Mr. Giffard, and which had, unfortunately, only a capacity of 28,000 cubic feet. I had already used this balloon for an ascent, executed for the benefit of the Arène de la Rue Monge.

That balloon was fitted up in a more scientific manner, the appendix being also firmly attached with rope, so that the pressure of the wind could not let a single puff of gas escape. The equatorial ropes were attached together and connected by means of little pulleys, the pulleys being connected by ropes, and so on till the whole of the network ended in three large ropes. This machinery worked admirably well, but the material of the balloon was not fit for the purpose. After two or three weeks' standing, the company was dissolved, and the balloon was sent free into the air. Captive observations were not so useful as had been hoped; that partial failure was owing to the unfitness of officers entrusted with the duty of making observations, and of the men employed in the drawing of the ropes. Nothing of the kind would have happened if Government had accepted the offers made by Mr. Giffard before the beginning of the war. That great engineer had offered to spend 40,000*l.* in the construction of a large balloon of 15,000 cubic metres capacity, able to carry 40 persons to the height of a full kilometre, but the Government had refused this proposal because Mr. Giffard asked for a place in the Champs Elysées, where it would have been necessary to displace a few shrubs.

When the investment of Paris was completed, the question naturally arose of using balloons for carrying messages, the resolution having been taken by the minister, M. Rampont, Post-office Director, to summon to his office several aëronauts, Nadar, Artoise, myself, and a few gentlemen supposed to be acquainted with aërostatics; and the ascent was decided upon in a long discussion.

The first who ascended, was Durioff with his own balloon, famous from several ascents. Durioff started up into the air early in the morning, and employed an immense lifting power, the wind blowing strongly besides, and Durioff disappeared like a dream. He was alone in his car, carrying a bag of letters, with plenty of ballast; I protested in the most urgent manner against sending into the air a single man unassisted, but without any success. The advice was neglected in consequence of the success of the first operations. Reverses were necessary to call postal authority to a better sense of the real state of things. M. Garnier Pagès, a member of the new Government, invented the carrying by balloons of aërial pigeons, and the second balloon ascent was the occasion of the first pigeon expedition.

One of the aëronauts known to our readers is Mangin, the proprietor of the unfortunate "Union," of which the wreck was fully described, who tried an ascent a few days after Durioff. He made a foolish agreement with the Post Office, to carry with his poor worn-out balloon a weight of 1,000lbs., but the balloon was unable to retain a single puff of gas, and the attempt was doomed to failure.

Two or three days afterwards, Mangin tried another ascent with the "City of Florence," a large balloon of 1,200lbs. capacity and belonging to Eugène Godard.

The "City of Florence" was inflated and fitted up by its proprietor, and left the ground on the morning of a clear day, with a light north-easterly wind. It carried with Mangin a medical man practising at Lyons, with a special mission from the Government for the eastern departments. The ascent succeeded very well, and Dr. Lutz was landed safely. But the landing of Lutz gave rise to a singular circumstance. A Prussian spy, having read in the papers that Lutz had come down from the heavens, presented himself at Dijon as the real Lutz, and acted in accordance with that suggestion. The fraud was not discovered without some delay and some trouble, but owing to some peculiar circumstances it was at last exposed, the false Lutz was seized, tried by a court-martial, condemned to death, and shot on the spot.

Amongst singular ascents one was executed two or three days afterwards by Louis Godard, carrying with him two merchants. Godard's balloon being too small for the purpose, he fixed one additional balloon to the end of a long narrow piece of wood, and in the middle of that long singular bridge there was a second balloon of no more than 100 cubic metres. The floating of this extraordinary trio created a great deal of amusement among our Belgian people, and is in itself an aërial aëronautical success; Godard landed near Nantes, where the Prussians had not yet set their feet.

Next to Godard's singular ascent, we must mention the one executed by Trignot for carrying Gambetta to his post at the head of the Government. An accident took place in the air while it was open, and the balloon emptied itself at an extraordinary rate, landing, against the will of the aëronauts, in Prussian territory. If sharpshooters had not come to the rescue, Gambetta would have been made a prisoner. Kératry was in the same manner sent in a balloon, and succeeded in escaping after some adventurous feats.

We must mention the ascent conducted by the elder Tissandier, as well as the one conducted by his younger brother. The first of these two ascents was remarkable for the firing at it by the Prussians when the balloon was passing over Versailles. Tissandier, as well as his brother, fell beyond Prussian territory, but not far from the enemy's force.

From the time of the landing up to the present moment, the brothers Tissandier have tried twice to return to Paris; but they ascended from Tours, which is a bad station for such a purpose. The first time their balloon was sent towards the south; the second time it ascended too high, and the brothers were conducted into a frozen cloud, which compelled them to come down. This second ascent was tried during the night, which is a decidedly awkward time, as an aërial traveller is unable to find his way to the land.

Returning to Paris will be tried, however, and is a great object to be attained, but for success to be secured requires more powerful means. I must not omit my own arrival in Belgium in a balloon. The "Egalité," which I employed on that occasion, had a younger brother called "Liberté." The "Liberté" was inflated with pure hydrogen, prepared specially for the purpose. It was the old captive of the Universal Exhibition, fitted up and carefully repaired for the purpose. "Liberté" was intended to carry ten persons, besides 3,000lb. weight of letters. It had two cars attached, the one fastened to the other by eight ropes. The upper car was intended for passengers, the lower one for letter-bags. Everything had been carefully prepared; bags of sand had been attached round the upper car, and a hole had been cut into the bottom to permit communication between the two cars. Unhappily, when the process of inflation was half finished, the wind began to blow with such violence that people holding the net let the ropes loose with so much force that the balloon escaped, turned round like a whirlwind, being lost in a minute in the clouds, and leaving thousands of spectators in consternation. "Liberté" was seen turning round two or three times again between different strata of clouds, and was finally observed turning no more, ascending no more, but falling straight like a meteoric stone. The fall took place within the Prussian lines, and it remained in the hands of the Prussians, who were enabled to repair and to use it for their purposes.

Seeing that I was unable to recover my balloon, I managed to get another constructed. The new balloon, though smaller than "Liberté," was larger than any other balloon in existence in Paris. It had a measurement of 3,000 tons instead of 2,000, the average. The ascent was delayed by an accident which happened during the process of inflating; a hole was discovered round the appendix, and the valve was open. For the three following days the weather was unfavourable, and the passengers were obliged to come back every morning, but the following morning several thousand people witnessed the ascent, which was very successful. After having landed in Belgium, I came to London on my way to Tours, and purpose shortly attempting to re-enter Paris by the same means.

W. DE FONVIELLE

SCIENTIFIC SERIALS

Annalen der Chemie und Pharmacie, viii. Suppt. Bd. 1 Heft. This number opens with a paper "On the occurrence of Ammonio-Magnesic Sulphate in the lagoons of Tuscany," by Dr. O. Popp, who has observed that a double salt of ammonic and magnesic sulphates is of constant occurrence, together with ammonic sulphate and boric acid, in the lagoons. He also remarked that the relative amounts of boric acid and ammonic sulphates are inversely proportional, so that those containing large quantities of boric acid contain but little ammonic sulphate, and *vice versa*. The salt, which separates out either during the concentration of the water or in the crystallising vessels, is obtained pure by recrystallisation in forms belonging to the monoclinic system, and of the composition

$$Mg\,SO_4 + (NH_4)_2\,SO_4 + 6\,O\,H_2.$$

In the natural double sulphate Mg is often replaced by the isomorphous Mn and Fe.—"On the origin of the Boric Acid in the Fiumaroles of Tuscany" is by the same author. After a criticism of the theories of Dumas and Bolley on this subject, he quotes the observations of Woehler and St. Claire-Deville, that boric nitride heated in the presence of aqueous vapour is decomposed into boric acid and ammonia, and that at a high temperature boron and nitrogen combine directly; they remarked that the presence of ammonia salts together with boric acid in volcanic craters and the lagoons of Tuscany might be due to such a decomposition. This the author also considers to be the probable explanation, and assumes that boric nitride is present in these volcanic localities, which comes in contact with water at a high temperature, forming boric acid and ammonia; this latter combines with sulphuric acid, formed by a process of roasting from the layers of pyrites, or of coal containing pyrites, which would also account for the presence of marsh gas and free hydrogen in the lagoon gases.—"On Chloranil and Bromanil," by J. Stenhouse. A modification of Grœbe's method of preparing chloranilic acid is described. Chloranilic ether was obtained by the action of ethylic iodide on the silver salt. Nitric acid of sp. gr. 1·45 oxidises chloranilic acid to chlorpicrin and oxalic acid. By the action of bromine on chloranilic acid a compound of the formula $C_6\,Br_8\,Cl_3\,O\,H$ was obtained. Bromanil is readily obtained by the action of a mixture of one part iodine and two parts bromine on phenol. Bromanilic acid was prepared in a similar manner to chloranilic, and in all its reactions found to be analogous. A compound, $C_6\,Br_{11}\,O\,H$, was obtained by the action of bromine on it.—"On Coumarin, Hydrocoumarin, and Hydrocoumarinic Acid," by C. Zwenger. The author observes that the preparation of coumaric acid from coumarin is attended with considerable difficulty, inasmuch as the acid is first formed at a temperature at which the potash readily causes a further decomposition. A most characteristic and delicate reaction for coumaric acid is the fine pea-green colour of its solutions when viewed by reflected light, and which is perceptible when only traces even of the acid are present. As is well known, melilotic acid is obtained by the action of nascent hydrogen *in excess* on coumarin; the author finds, however, that if the coumarin be kept in excess a new acid, which he calls hydrocumarinic, is formed. This acid is derived by the addition of H_2 to two molecules of coumarin, and has the composition $C_{18}\ H_{18}\ O_6$. On heating in a water bath, or even on heating with dilute HCl or $H_2\,SO_4$, it loses water and is converted into the anhydride $C_{18}\ H_{14}\ O_4$, which may also be obtained directly from coumarin.—"A New Method of Synthesis of the Organic Acids," by M. Berthelot. On allowing acetylene mixed with air to remain in contact with dilute potash solution for six months, the acetylene was found to have been converted partly into acetic acid and partly into a bituminous substance, containing C H and O. Employing a solution of chromic anhydride, a more perfect conversion of the acetylene to acetic acid took place. Allylene treated in the same way gave propionic acid; but it is probable that an intermediate compound $C_3\ H_4\ O$ is formed by the direct addition of O, and which should also be obtained by the abstraction of OH_2 from propionic acid. Propylene gave propionic acid, acetone, and acetic acid; even carbon was oxidised by this reagent, giving small quantities of oxalic acid. It deserves notice that a solution of pure chromic anhydride is a much gentler oxidising agent than the usually employed mixture of sulphuric acid and potassic dichromate, probably partly by reason of its evolving a smaller proportion of oxygen. By its decomposition, free oxygen and chromic chromate, a salt corresponding to ferric sulphate, are formed:

$$5\ Cr\ O_3 = Cr_2\ O_6\ 3\ Cr\ O_2 + O_3$$

"On the synthesis of aromatic acids, by A. Wurtz." By the action of $Na_2\ Hg$ on a mixture of chlorocarbonic ether and bromtoluol, the ethers of toluylic and isotoluylic acids were formed, which is explained by the fact that bromtoluol is a mixture of two isomeric compounds. On treating a mixture of chlorocarbonic ether and benzylic chloride, the following more complicated reaction takes place:

$$2\ C_7\ H_7\ Cl + CO\ Cl\ OC_2\ H_5 + 3\ Na = 3\ Na\ Cl + H + C_{14}\ H_{13}\ CO\ OC_2\ H_5$$

(Dibenzylcarbonic ether.)

The first action of the sodium is probably to form chlorinated dibenzyl,

$\left\{\begin{matrix} CH_2\ C_6\ H_5 \\ CH\ Cl\ C_6\ H_5 \end{matrix}\right.$ from 2 mols. of benzylic chloride, and this by the action of Na and $CO\ Cl\ OC_2\ H_5$, becomes converted into

$\left\{\begin{matrix} C\ H_2\ C_6\ H_5 \\ C\ H\ CO\ OC_2\ H_5\ C_6\ H_5 \end{matrix}\right.$ By the dry distillation of its lime salt, stilben and dibenzyl are obtained:

$$2\ (C_{15}\ H_{13}\ O_2)\ Ca = Ca\ CO_3 + CO + C_{14}\ H_{12} + C_{14}\ H_{14}$$

—"On the molecular weight of some Protoxides," by A. Ladenburg. This is really so important and interesting a paper that it is difficult to give an idea of its contents in the short space at our command. Although the determination of the vapour density is still the most certain method of establishing the molecular volume, it cannot be denied that the true interpretation of chemical metamorphoses also affords a means of fixing the molecular formulæ of compounds. The author also considers this to be the case in those reactions which cause a change of type, viz., in cases of direct addition. The molecular volume of the resulting product permits in many cases at least an inference as to the formula of the unsaturated compound. For instance, from the passage of ferrous into ferric chloride, he believes himself justified in drawing the conclusion that $Fe_2\ Cl_4$ is the formula of the former, $Fe_2\ Cl_6$ being that of the latter, as is proved by its vapour density. The same may be urged of Cr and Mn compounds, although not with the same certainty, and it was to obtain further proofs in this direction that the author strove. By the action of a mixture of 3 eq. acetic and 1 eq. formic acid on manganous carbonate, a compound $Mn_2\ (C_2\ H_3\ O_2)_3\ C\ H\ O_2$ was obtained, but it is not placed beyond all doubt that this is not a mixture of two salts. A series of experiments with tin compounds were then undertaken with the view to ascertain whether the compound $Sn_2\ Cl_6$, intermediate between $Sn\ Cl_2$ and $Sn\ Cl_4$ could not be obtained. By the action of Br on $Sn\ Cl_2$, $Sn\ Cl_2\ Br_2$, $Sn\ Cl_3\ Br$, and $Sn\ Br_3\ Cl$ were formed, revealing the curious fact that similar molecules so react on one another that dissimilar molecules result:

$$Sn\ Cl_2\ Br_2 + Sn\ Cl_2\ Br_2 = Sn\ Cl\ Br_3 + Sn\ Br\ Cl_3.$$

No experimental proof of stannic triethide being $Sn_2\ (C_2\ H_5)_6$ and not $Sn\ (C_2\ H_5)_3$ had hitherto been adduced; it was prepared by the action of Na on $Sn\ (C_2\ H_5)_3\ I$, and its vapour density determined and found to agree with that required by $Sn_2\ (C_2\ H_5)_6$. The action of Cl on stannic triethide is as follows: $Sn_2\ (C_2\ H_5)_6 + Cl_8 = 2\ Sn\ (C_2\ H_5)_2\ Cl_2 + 2\ C_2\ H_5\ Cl$. By the action of I first $Sn\ (C_2\ H_5)_3\ I$, and then $Sn\ (C_2\ H_5)_2\ I_2$ is formed. By the action of sodic ethylate on $Sn\ (C_2\ H_5)_3\ I$ stannic ethylotriethide $Sn\ O\ C_2\ H_5\ (C_2\ H_5)_3$ was obtained. There then follow a number of similar experiments on stannic methides, &c.—"On Schiel's chloraluric acid," by N. Lubavin. Schiel described an acid obtained by the action of chlorous acid on uric acid, to which he gave the formula $C_{14}\ H_{11}\ N_6\ Cl\ O_1$ (old atomic weights); this Lubavin proves to be a mixture ammonic chloride and parabanic acid. He also mentions an oxalate of urea of the composition $C\ O\ N_2\ H_4, C_2\ H_2\ O_4 + O\ H_2$ the formula of the ordinary oxalate being $2\ C\ O\ N_2\ H_4.\ C_2\ H_2, O$. In all the text-books 120° is given as the fusing point of urea; he finds it to be 132°.—"On derivatives of Anethol," by A. Ladenburg. On fusing anethol (oil of anise) with caustic potash, the following reaction takes place:—

$$C_6\ H_4 \left\{\begin{matrix} O\ C\ H_3 \\ C_3\ H_5 \end{matrix}\right. + K\ O\ H = C_6\ H_4 \left\{\begin{matrix} O\ H \\ C_3\ H_5 \end{matrix}\right. + C\ H_4\ O$$

Treated with $P\ Cl_5$ H becomes replaced by Cl

$$C_6\ H_4 \left\{\begin{matrix} OCH_3 \\ C_3\ H_5 \end{matrix}\right. + P\ Cl_5 = C_6\ H_4 \left\{\begin{matrix} O\ C\ H_3 \\ C_3\ H_4\ Cl \end{matrix}\right. + H\ Cl + P\ Cl_3$$

This body treated with alcoholic potash loses H Cl and gives $C_{10}\ H_{10}\ O$, a liquid boiling at 240°. All experiments to replace the Cl in chloranethol by $C_2H_3O_2$ failed. Anethol combines directly with Br_2.—"Researches on Vanadium," by Henry E. Roscoe. In this communication are described vanadic tribromide and oxytribromide; also a large number of meta, ortho and pyrovanadates, among others the artificially prepared vanadinite. As this paper appeared in English in the Chemical Society's Journal, it has already been noticed in this journal.—"On the second fundamental theorem of the mechanical theory of heat and its application to several decompositions," by Dr. A. Horstmann. The author has given a popular treatment of the mechanical theory of heat, as he considers that although of the greatest interest to chemists, it has remained comparatively unknown to them by reason of its requiring a somewhat high mathematical knowledge. The decompositions to which it is applied are those of ammonic chloride and calcic carbonate by heat, and also the expulsion of the water of crystallisation from hydric disodic phosphate.

SOCIETIES AND ACADEMIES

LONDON

Geological Society, November 23.—Mr. Joseph Prestwich, F.R.S., president, in the chair.—1. "On some points of South-African Geology." Part 1.—By Mr. G. W. Stow. In this paper, which was illustrated by numerous sketches, sections, tables, and specimens, observations were made on the stratification of the Jurassic beds of Sunday's and Zwarktop's rivers, resulting from researches made by Mr. Stow, with the view of determining the exact position of the several species of fossils found at the exposures on the cliffs of these rivers, and from this the sequence of the various beds. He indicated the existence of at least nine separate fossiliferous bands, pointing out the relative positions of the several *Trigonia*-beds, Hamite-beds, Ammonite-beds, &c. He next treated of the so-called Saliferous beds of the district, and gives his reasons for regarding them as later in age than the *Trigonia*-sandstones above alluded to, and therefore not equivalent to that part of the series named "Wood-beds" by Dr. Atherstone. Other researches of the author related to the Tertiary beds both inland and on the coast. He distinguished three zones on the coast later in date than the high-level shell limestones (Pliocene?) of the Grass Ridge and other parts of the interior. One of the coast-zones he named the *Akera*-bed, from the prevalence of a delicate species of that genus. Another zone was described as following the river-valleys in the form of raised terraces, characterised by the presence of a large *Panopæa*. The latest shell-banks have been thought to be kitchen-middens, but the author regarded them as shore-deposits in place. The author concluded by tracing the probable climatal and geographical changes in this region during geological times, and indicated, as far as his material allowed, the probable migrations of the Mollusca, especially of the *Venericardia* characterising the Pliocene Limestone. Mr. Gwyn Jeffreys remarked that all the shells belonging to the genus *Akera* which he had examined were shallow water or littoral shells. Dr. Duncan remarked on one of the corals as being of a well-known Crag form, the *Balanophyllia calyculus*. Mr. Searles Wood, jun., observed that there appeared some probability on the face of the paper of the shells of the older post-tertiary beds denoting a warmer climate than the present, instead of, as here, a colder.—

2. "Note on some Reptilian Fossils from Gozo." By Mr. J. W. Hulke, F.R.S., F.G.S. The author described the remains of two reptiles said to have been brought from Gozo by the late Captain Strickland. One of them was a fragment of the symphysial part of the slender mandible of an *Ichthyosaurus*, having teeth of precisely the same character as those of the form from the Kimmeridge Clay described by the author under the name of *Enthekiodon*. For this species the name of *Ichthyosaurus gaudensis* was proposed. The other was the skull of a species of crocodile, for which the author proposed the name *C. gaudensis*. Dr. Duncan suggested that the Ichthyosaurian fossil might be derivative from some secondary rock. He mentioned that Dr. Leith Adams had once sent him an *Aspidiscus cristatus* from the Hippurite Limestone, which was stated to have come from Malta. To account for this, he suggested that the Miocene of Malta might have been supported on beds of Cretaceous age, so fossils from that source might have become indebted in the coral reefs of the later date. Capt. Spratt expressed a doubt of the fossils having really come from Gozo. He did not recognise the cretaceous-looking matrix among any of the rocks of that island, with all of which he was acquainted. The nearest approach to that kind of rock was to be found in the lowest of the deposits near Cairo, which were probably Eocene. Prof. T. Rupert Jones suggested an examination of the Foraminifera in the matrix, with the view of determining its Secondary or Tertiary age. He mentioned the occurrence of rolled nodules of older rocks in beds of later age at Gozo. Mr. Busk stated that a stone of similar character to the matrix occurred in Malta, if not in Gozo, but probably in both. Mr. Hulke, in reply, observed that he had in this paper intentionally left the stratigraphical part of the question untouched, and confined himself to the palæontological aspect of the remains.—3. "On the discovery of a 'Bone-bed' in the lowest of the 'Lynton Grey Beds,' North Devon." By F. Royston Fairbank, M.D. In this paper the author called attention to the occurrence of a thin bed of rock to the west of the harbour of Lynmouth, containing an immense number of fragments of bone, some of them of large size, and associated with massive bodies which he regards as coprolites. The author proposed to call this the "Lynton Bone-bed;" and he thought that its discovery might throw some light on the relative age of the whole series of rocks of North Devon. Mr. Whitaker had examined the beds in company with Mr. Wetherell. He did not agree with the author as to the amount of iron in the beds. The bone-remains appeared to him to be those of *Steganodictyum*, which had already been found in the lowest of Devonian beds. He was not prepared to accept the nodules described as being undoubtedly coprolites. Mr. Valpy stated that there were at least a dozen beds on different horizons of much the same character as that described along the coast of North Devon, an account of which had already been published at Ilfracombe.

London Institution, November 24.—Mr. H. W. Field, F.C.S., in the chair. Prof. Morris, F.G.S., delivered a lecture "On the Precious Metals and their Distribution." Having indicated the principal sources of the gold and silver worked by the ancient nations, he explained the distinguishing characters of these two metals, and dwelt at length on their mode of occurrence, geographical distribution, and geological position. Gold usually occurred in nature in the metallic condition, nearly pure or alloyed with certain metals, while silver was found in combination with various elements, and but rarely in the native state. The distribution of gold throughout the world was illustrated by a large map, on which the known gold-yielding localities were plainly marked. Gold was found in rocks, quartz veins, and alluvial deposits. The silurian rocks and the granites associated with them furnished the chief supplies, but the cretaceo-oolitic rocks of Peru, Bolivia, and California, when traversed by dioritic igneous rocks, were also auriferous; showing, according to Mr. David Forbes, that there had been two well-marked epochs of gold intrusion. From both formations, but specially from the silurian, the gold occurring in alluvial deposits had been derived by the enormous erosion which the rocks had undergone at a comparatively late geological period, namely, the Newer Pliocene. The remains of extinct mammalia discovered in the deposits of the Urals, and also in those of Australia, had satisfactorily fixed their geological position. In Australia and California subsequent volcanic flows had covered thick accumulations of auriferous gravels, and had diverted the courses of many streams, so that they no longer conformed to the old valleys. The minerals mistaken for gold were enumerated and their distinguishing chemical and physical characters were indicated. In conclusion, the lecturer alluded to certain points relating to the use of gold in coinage, and called special attention to the brittleness produced by the presence of minute quantities of palladium in the standard alloy. The lecture was illustrated by numerous diagrams and maps, models of famous nuggets, gold-washing apparatus, and many beautiful specimens of native gold.—Dr. Odling's educational lectures "On Chemical Action," delivered on Mondays at four o'clock, continue to attract crowded audiences, comprising a large number of boys and girls from the schools of London and its suburbs.

Linnean Society, December 1.—Mr. Bentham, president, in the chair.—"On the Source of Radix Galangæ minoris of Pharmacologists." The source of the Greater Galangal has long been known to be *Alpinia galanga*, Linn.; that of the Lesser Galangal has been more obscure. Galangal is not used in English medical practice, and on the Continent has become almost obsolete; its export from China is, however, considerable, and is rapidly increasing. During an expedition to the Island of Hainan, a quantity of the root which provides the Lesser Galangal was observed exposed to the sun in baskets. On a subsequent occasion the plant itself was discovered at a spot six miles inland, at an elevation of 100 feet above the sea, growing in a dry red soil, the result of volcanic action. Here it was evidently planted, but was subsequently detected growing wild in jungles in the same island. Twenty or thirty stalks spring from each root, but rarely more than one or two bear flowers. The fruit appears to be the bitter kind of Cardamom figured by Mr. Hanbury. The plant is closely allied to *Alpinia calcarata*, which flowers readily in the Calcutta Botanic Gardens; but was determined by Dr. Hance to be a perfectly distinct and well-defined species, to which he gave the name *Alpinia officinarum*. A diagnosis of the plant was also given by Dr. Hance.—Supplementary note on the Chinese Silkworm Oaks, by Dr. Hance.

MONTREAL

Natural History Society, October 31.—The President, Principal Dawson, in the chair. Mr. A. S. Ritchie read a paper entitled "Aquaria Studies," Part 2. In a previous paper the author had described the habits of some of the larger inhabitants of his aquarium. In the present sketch an attempt was made to illustrate the peculiarities of the microscopic denizens of the same. The structure of some of the lowest forms of vegetable life was first illustrated, and some points in their physiology described. The first example of the animal kingdom selected was the Amœba or Proteus. In this animal we see a creature devoid of muscular or nervous system, with no head, no stomach, or alimentary canal. Its body consists of a jelly-like substance, of irregular shape, from any part of which finger-like processes are at times protruded. It lives by absorption, and can improvise a stomach from any part of the exterior of its body. The Amœba is one of the very lowest forms of animal life. The lecturer then proceeded to explain the structure and habits of other microscopic animals, a little more complex than the preceding. Among these were the blue Stentor, the bell animalcule (*Vorticella*), the glutton (*Lurco*) Rotifers, or "wheel bearers," Paramœcium, the four-horned Cyclops, and other microscopic animals. He stated that he had frozen water, containing Rotifers, solid, and upon melting the ice the Rotifers were as lively as ever, also that they could endure a considerable degree of heat. A large diagram, with figures of the several plants and animals spoken of, materially helped to illustrate the paper, which will shortly appear *in extenso* in the next number of the *Canadian Naturalist*.—Mr. Billings then made a communication on the bones of a whale lately discovered at Cornwall, Ont., of which the following is an abstract:—"Several months ago Mr. Charles Poole, of Cornwall, wrote to the secretary of the Society that a large skeleton, resembling that of an Ichthyosaurus, had been found in that neighbourhood by the men engaged in excavating clay for brick. In another letter he stated that Mr. T. S. Scott, architect, of this city, had procured the lower jaws. On receipt of this information, Mr. Billings called upon Mr. Scott, who very liberally presented the jaws to the Geological Museum. Mr. Billings then went up to Cornwall and obtained from Mr. Poole the bones which were in his possession. These were discovered in the Post-pliocene clay formation, about sixteen feet below the surface. They are those of a small whale closely allied to the white whale, *Beluga leucas*, which lives in the Northern seas, and at certain seasons abounds in the Gulf and lower part of the St. Lawrence. The lower jaws are nearly perfect. The skull and upper jaws are much damaged, and some of the parts lost. Thirty-five of the vertebræ, the two shoulder blades, most of the ribs, and a number of small bones were collected. The length of the animal was probably about fifteen feet. The lower jaws have the sockets of eight teeth upon the right side, and of seven on the left. The number of teeth in the upper jaw could not be ascertained. In the head of a white whale belonging to the cabinet of M'Gill College, there are nine teeth in the right lower jaw, and eight in the left. The teeth of the fossil, judging from the size of the sockets, were longer than those of the white whale. In 1849, a small whale was discovered in Vermont about twelve miles south of Burlington, in a railway cutting, through a deposit of clay of the same formation as that of Cornwall. Judging from the figures and description published in *Silliman's Journal* by the late Professor Thompson, there can be little doubt that ours is the same species which he described, and which he called *Beluga vermontana.* Another specimen consisting of about half of the backbone, was discovered several years ago near the city of Montreal, and is now in the Museum of the Geological Survey. The locality at Cornwall is about half a mile from the railway station, sixty feet above the St. Lawrence, and over two hundred feet above the level of the sea.—The President, in inviting a discussion on the phenomena observed during the recent earthquake, said that there were records published or preserved of the appearances observed during 83 earthquakes in Canada and neighbouring parts of N. America. A severe shock was felt in Canada in 1860, an account of which might be found in the *Canadian Naturalist* for that year. Many of the phenomena noticed in 1870 were observed in the shock of 1860. Judging from the facts on record, there would seem to be a periodicity in earthquakes. They seem to occur much oftener in autumn and winter than in spring or summer, and between the 60th or 70th years of a century. On this ground he had stated that the shock of this year might prove to be the beginning of a series, if the law of periodicity holds good. A slight shock was, however, felt in Canada in the spring of 1864. The president next referring to the causes which produce earthquake, said that here there are no centres of active igneous agencies, as in Southern Italy and elsewhere. He suggested the idea that large masses of sediment are drained off by rivers from this continent and deposited on the Atlantic coast, and when, in addition to this, a pressure amounting to many millions of tons of atmospheric air is removed from the denuded portion, vibrations occur from long-continued tension of the earth's crust, and finally a break takes place. It was found that during the last earthquake the mercury in the barometer was an inch lower than the average. Dr. Smallwood gave a description of peculiar phenomena observed in the heavens before and after the earthquake. Among these were noticed several clusters of spots on the sun's disc in connection with peculiar auroral displays. He exhibited diagrams showing the barometrical and thermometrical appearances presented before and during the shock. During the continuance of the vibration the descent of the mercury was most marked in this respect, confirming Dr. Dawson's view. From telegrams received by the courtesy of Mr. Dakers, it would appear that the first shock was observed at Owen Sound, at 10.52 A.M. local time, and the latest at St. John's, N.B., at 11.45 A.M. local time. Accounts were received also from Toronto, Montreal, Quebec, and intermediate places. Judging from the accounts received, the extent of the vibration thus recorded would appear to have been from S.W. to N.E., and the shock to have occupied fifty-three minutes of time in traversing the 840 miles, without calculating for the difference of longitude between the places. This would give a rate of about sixteen miles per minute, but if the differences of longitude were calculated the rate would be about thirty-two miles per minute. This last estimate would agree nearly with that given by Humboldt and Mallet. The width or amplitude of the vibration, judging only by telegrams received by the speaker, would appear to have been some 340 miles. After some remarks by Dr. J. B. Edwards and others, the meeting adjourned.

Halifax, Nova Scotia

Institute of Natural Science, November 14.—J. M. Jones, F.L.S., president, in the chair. Rev. D. Honeyman, F.G.S., read a paper, entitled "Record of Observations on the Geology of Nova Scotia from 1855, Part I.;" from which it appeared that Dawson's "Acadian Geology," first edition, was published in 1855, and that in this work the author of the present paper was introduced as an explorer in the Nova Scotian field. His attention had been chiefly directed to the "Silurian (?) and Devonian rocks," so designated in that volume, and to the lower carboniferous conglomerates, grits, sand-stones, argillites, limestones, and gypsums. He had also made gleanings in the coal field. Since that period Dr. Dawson and the author, with the aid and advice of Sir R. Murchison, Hall, Salter, and Barrande, had deprived the Devonian system of its ascendancy in Middle and Eastern Nova Scotia, and Cape Breton; taking away the mark of interrogation from the Silurian and affixing it to the Devonian. This was done chiefly by a thorough investigation of the palæontology and geology of the thoroughly typical district of Arisaig on the south-east coast of Northumberland Strait, in the Gulf of St. Lawrence; and the application of this type to the geology of the province. It was shown by the author that while the fossils of the series of rocks of Arisaig had so great a resemblance to those of the British Silurian, that Mr. Salter could without hesitation designate the respective groups according to the British nomenclature; still, the series could be more satisfactorily and thoroughly compared with the Silurian of the United States; consequently, the Arisaig series were now arranged thus, in ascending order:—Oneida conglomerate, Medina sandstone, Clinton (Middle Silurian), Niagara limestone, Lowes Helderberg (Upper Silurian), Oriskany sandstone (?) (Devonian). In this locality these are overlaid unconformably by conglomerate with interstratified traps and limestones (Lower Carboniferous). The Silurian and Devonian (?) have been thrown into a synclinal by greenstone and amygdaloids of Lower Carboniferous age. The Arisaig fossiliferous series are bounded on the north by Northumberland Strait, on the south by mountains formed of another series of the same age, but different from the other in being highly metamorphic and, apparently, non-fossiliferous; the lowest member of the series is a *conglomerate* with cleavage. This series has been elevated by the upheaval of syenite. These conjointly attain to an elevation of from 1,000 to 1,010 feet above the sea level, according to Captain Bayfield's measurement; this being about the highest elevation of mountains in Nova Scotia. While numerous localities named in Dawson's "Acadian Geology," and others discovered by the author since 1855, have fossiliferous rocks of the Arisaig type, the general character of the rocks of the principal ranges of the mountains of Nova Scotia is Arisaig metamorphic non-fossiliferous. The President read a paper "On the Diurnal Lepidoptera of Nova Scotia, Rhopalogera, Part I." The following species were common in the province, *Papilio turnus* Linn.; *Pieris oleracea* Harris, *P. rapæ* Boisd., *Colias philodice* Godt., *Argynnis aphrodite* Fabr., *Argynnis myrina* Cram., *Melitæa tharos* Cram., *Grapta C. argenteum* Kirby, *Vanessa antiopa* Linn., *Pyrameis cardui* Linn., *P. huntera* Smith, *Nymphalis arthemis* Drury, *Erebia nephele* Kirby, *Satyrus alope* Fabr.; while *Danais archippus* Fabr., *Melitæa ismeria* Boisd., *Grapta interrogationis* Godt., *G. comma* Harris, *Vanessa J. album* Boisd., *V. milberti* Godt., *Pyrameis atalanta* Linn., *Nymphalis disippus* Godt., *Debis Portandia* Fabr., were rare. The author dwelt upon the introduction of *Pieris rapæ* into this part of the Canadian dominion within the last few years, and alluded to its abundance last summer in the neighbourhood of Halifax, where it did an immense amount of damage to the cauliflower crops. He mentioned the probable benefit that would arise from the introduction of the house-sparrow of England (*Pyrgita domestica*) that great enemy of caterpillar life, which would amply repay the trouble and expense of importation. At the present time the caterpillars were almost free from molestation, and it was but proper, when possible, on the introduction of an insect pest, to introduce also its known enemy. The author had observed that even in so small a country as Nova Scotia many species of butterflies were very local in distribution, and species quite common on one side of the province were altogether unknown on the other, although the distance between such positions was not more than thirty miles. Several Hesperians were yet unnamed, and these when identified with some Lycænians, would be included in Part II.

Wellington, New Zealand

Philosophical Society, September 17.—Dr. D. Hector exhibited a preparation showing the egg of the large Kivi (*Apteryx australis*) *in utero.* The bird had recently died in confinement, and was sent to the museum to be skinned. The egg, though full-sized, is soft, and squeezed out of shape by the pressure against the pelvic bones.—"Critical Notes on the Ornithological Portion of the Rev. R. Taylor's recent work on New Zealand."

by W. L. Buller, F.L.S.—"On the Ornamental Cultivation of Native Shrubs," by T. H. Potts and William Gray, Canterbury.—"Notes on New Zealand Birds," continued, by T. H. Potts.—"On the Nomenclature of New Zealand Rocks" and "Notice of some New Mineral Forms in the Museum," by E. H. Davis, F.L.S.—"On the Absorption of Sulphur by Gold," by W. Skey, Government analyst. The author of this paper, while recently investigating the causes of the reported loss of gold at the Thames gold fields during its extraction from the ore, found the gold is acted on by sulphuretted hydrogen, and thus a sulphide is formed which tarnishes the surface. Also that gold combines with free sulphur at a temperature of 212° Fahr. Gold thus sulphurised on the surface will not amalgamate with mercury. The loss of gold is not altogether due to the condition of the mercury, as has hitherto been supposed, as he has found this sulphide on the surface of native gold of every degree of purity.

Vienna

I. R. Geological Institution, Sept. 30.—During the summer season the geologists of the Institution were partly occupied with the survey of Northern Tyrol from the environs of Kufstein, along the valley of the Inn westwards as far as Innsbruck, and partly on the military frontier between Barziasch on the Danube, and Brod in Slavonia. Messrs. Foetterle and Fr. v. Hauer, invited for this purpose by the Roumanian Government, investigated also parts of the Wallachian territory, and studied more particularly some sections between Bucharest and Kronstadt in Transylvania. Very interesting results were obtained here. The large portion of Southern Wallachia seems mostly covered with loess; but a boring at Bucharest, for an artesian well, perforated up to the depth of 250 metres beyond the loess nothing but strata of clay and sand, belonging to the Congeria-beds, a freshwater deposit which, in the Vienna basin, forms the highest member of the Miocene formation. Farther up towards the north the same strata constitute a broad zone of mountains of lower elevation, which board the plain, and form a passage to the high mountain which separates Wallachia from Transylvania. Large masses of petroleum are here imbedded in the lower parts of the congeria deposits. Whilst, therefore, the Galician petroleum belongs to the Eocene Carpathian sandstones, the Wallachian petroleum is of the upper Miocene age, and the strata which contain it abound in characteristic fossils of our congeria beds. Immediately below these beds follows the salt formation, consisting of salt clay, with large masses of rock salt, which is worked in the mines of Telega, Sylatina, Okna, &c. The higher mountains are formed chiefly of Eocene strata, partly sandstones, partly coarse conglomerates, with enormous boulders of jurassic limestone. These Eocene strata underlie immediately the salt formation in the Bucsecs mountain; they are upheaved to the height of more than 8,000 feet above the level of the sea. The crystalline rocks which form the nucleus of the Fogarasch mountains in Transylvania finish eastward in the neighbourhood of Ruckur, in the Dibmovizza-valley. On the passage between Kronstadt and Sinaja they are no longer to be observed.—Dr. T. Schmidt, director of the Observatory at Athens, gave notice of the violent earthquakes of July 31, August 1 and 5, in Greece, and mentioned that the volcanic eruptions in Santorin, which began five years ago, continue up to the present day with undiminished force.—M. Herbech discovered in Eastern Transylvania, on the Nagy-Hagymas mountain, some red limestone, with the characteristic fossils of the famous upper triassic Hallstatt marble, among them the magnificent Ammonites Metternichii.—Count H. Wilcjek and Count G. Wurmbrand discovered last summer an old pile building (Pfahlbau) in the Atter Lake in Upper Austria, near Kammer. Stone implements, fragments of rough pottery, &c., were found in abundance at the bottom of the lake.

Imperial Academy of Sciences, October 6.—Professor Barth transmitted some communications from the Chemical Laboratory of the University of Innsbruck. These notices included the results of an investigation made by Prof. Barth on the reaction of fusing potash upon phenole, of an investigation of the bromophenolic acids, by M. Carl Tenhofer, and on some derivatives of gallic acid, by Professor Reynold.—Dr. S. von Basch presented a memoir on the first chyle-ducts and the absorption of fat. The results of the observations made at the Central Observatory for meteorology and terrestrial magnetism during the months of July and August were laid before the meeting.

October 13.—M. Julius Peterin communicated a memoir on the formation of electrical annular figures by the current of the influence machine.—Dr. L. J. Fitzinger presented the fifth section of his critical revision of the bat family, relating to the genera *Nycticejus*, *Lasiurus*, *Amblyotus*, *Murina*, *Harpyiocephalus*, *Nyctiptenus*, *Æorestes*, and *Natalus*.—Dr. von Zepharovich, of Prague, communicated a notice of the crystals of cerussite lately found in the Galena mines at Kirlibaba. His paper contained accurate measurements of the crystals.—Dr. E. Brücke communicated a paper by M. A. Schapringer on the contraction of the *tensor tympani*.—A memoir was read by Professor Loschmidt, containing an account of experimental investigations on the diffusion of gaseous mixtures, by M. A. Wretschke.—And Dr. J. Peyritsch communicated some further observations on pelorism in the Labiatæ.

DIARY

THURSDAY, December 8.

Royal Society, at 8.30.—Report on Deep-Sea Researches carried on during the months July-September, 1870, in H.M. Surveying Ship *Porcupine*: Dr. Carpenter, F.R.S., and J. Gwyn Jeffreys, F.R.S.

Society of Antiquaries, at 8.30.—Autographs of Eminent Italian Princes: Dr. O'Callaghan, F.S.A.—On a Deed appointing Sir John Fastolf Governor of the Bastille, 3 Hen. V.: Mr. J. G. Nichols, F.S.A.

London Mathematical Society, at 8.—Further Remarks on Quartic Surfaces: Prof. Cayley.—On the Polar Correlation of two Planes, and its Connection with their Quadric Correspondence: Dr. Hirst, F.R.S.—On Systems of Tangents to Plane Cubic and Quartic Curves: Mr. J. J. Walker.—On the Order and Singularities of the Parallel of an Algebraical Curve: Mr. S. Roberts.

London Institution, at 7.30.—On Count Rumford and his Philosophical Work: Mr. W. Mattieu Williams.

FRIDAY, December 9.

Liverpool Naturalists' Field Club.—Lecture by Prof. W. C. Williamson, F.R.S.

SUNDAY, December 11.

Sunday Lecture Society, at 3.30.—On the Telescope and its Discoveries: Mr. R. A. Proctor.

MONDAY, December 12.

London Institution, at 4.—On Chemical Action (Educational Course): Professor Odling, F.R.S.

TUESDAY, December 13.

Royal Geographical Society, at 8.30.

Ethnological Society, at 8.—On Stone Implements from Africa: Sir John Lubbock, Bart., M.P.—On Stone Implements from the Cape of Good Hope: Mr. Edgar Layard.—Second Report on the Prehistoric Monuments of Dartmoor: Mr. C. Spence Bate.

Photographic Society, at 8.

Manchester Literary and Philosophical Society, at 7.

WEDNESDAY, December 14.

Society of Arts, at 8.—On a new Method of producing Durable Mural Paintings by Fictile Vitrification: Mr. Alan S. Cole.

Royal Microscopical Society, at 8.—On the Anatomy of *Ascarus lumbricoides*: Mr. B. T. Lowne, M.R.C.S.—Observations on the Aëroscope, or Air-dust Collector: Dr. Maddox.

THURSDAY, December 15.

Royal, at 8.30.

Chemical Society, at 8.—On some New Derivatives of Coumarin: Mr. W. H. Perkin.

Linnean Society, at 8.

London Institution, at 7.30.—On Count Rumford and his Philosophical Work: Mr. W. Mattieu Williams.

CONTENTS

Errata.—Page 76, first column, line 29 from bottom, for "high" read "low"; second column, line 8, insert after "winter," "—there atmospheric pressure is low;" page 92, second column, sixth note, for "Mr. Matthew Williams" read "Mr. William Mathews," and for "Mr. Williams" read "Mr. Mathews."

THURSDAY, DECEMBER 15, 1870

PRACTICAL PHYSICS

THE Vicissitudes of Families of Words, and especially of scientific nomenclature, would require another Burke to write their changeful history. Take, for instance, the word *Philosophy*,—how odd its present distorted meaning as compared with its literal sense, and how curious its alliance with such terms as Natural, Experimental, Mechanical, Chemical, and the like. Then, again, take *Science*,—how strange its present opposition to *Learning*, and how remarkable the adoption of the word *History* in conjunction with *Natural!* Most surprising of all, however, is perhaps the opposition set up between the words *natural* and *physical;* which has gone to such length that Prof. Huxley, in his recent Address to the British Association, could properly and intelligibly employ such a phrase as "those phenomena of nature which we call physical."

In French, the equivalent term for Natural Philosophy, "philosophie naturelle," is still sometimes used, and in a sense, if not coincident with, yet kindred to, that of its English representative; in German, however, the similar term, "Natur-Philosophie," has assumed a totally different meaning, and the word "Philosophie" by itself is, if possible, still farther from the English *philosophy*. For the latter word, in its English meaning, there is no equivalent whatever in German; while the occurrence of such expressions in English as Philosophical Instruments, co-existent with Moral Philosophy, strikes the German ear and intellect as insular eccentricity. But the German terminology is also in this respect not free from oddities. Thus, while "Experimentalische Physik" and "Theoretische Physik" (or sometimes "Mathematische Physik") cover nearly, although not precisely, the ground occupied by Experimental Philosophy and Natural Philosophy (in the orthodox sense) respectively; the word "physikalisch" has assumed a meaning opposed not to Moral but to Chemical, and a distinction has grown up between "physisch" and "physikalisch," corresponding to that between the English terms Natural and Physical.

To the terms just mentioned, Prof. Kohlrausch has now added a new one, on the title-page of a recently published little work, entitled, "Praktische Physik."* He thereby designates a series of practical exercises designed originally for the students who frequent the so-called "Physikalische Praktikum" in the University of Göttingen, for the purpose of being initiated into the use of physical instruments and the execution of physical operations. A work of this nature has long been a desideratum; although it has had a kind of forerunner in Prof. Frick's well-known "Physikalische Technik," *i.e.* Technical (or Operative) Physics, and to be distinguished from "Technische Physik," which means Physical Technology, or the application of Physics to manufactures and arts. Prof. Frick's work, however, of which three editions have appeared, was intended rather as an instruction in the making of lecture experiments and in the handling of the required apparatus, replacing in so far the older works of Abbé Nollet* and Sigaud de la Fond;† while the present work of Prof. Kohlrausch is designed as an initiation into original experimental measurements and researches. It has long appeared to the present writer as a kind of double drawback, inherent to current lectures as well as text-books on philosophy, that while, in all instances, more time or space is devoted to the description of apparatus and practical processes than is necessary or useful for the common student, they are yet, in this very respect, insufficient for the intending physicist. Taking in hand the best kind of treatises on Physics, whether of an entirely elementary or a more ambitious character, it will be found that a preposterous amount of space is taken up by drawings of instruments which the general student will never have to handle in his life, and by explanations of the manner in which certain procedures, measurements, and so forth have been taken, which it is practically equally useless for him to know, and which as a means of educating the mind have no value, while they tend to make science repulsive. On the other hand, the most voluminous works cannot but be pronounced, in this very respect, as deficient, if the wants of the young physicist are taken into account. Special works, like those of Profs. Frick and Kohlrausch, go some way towards supplying this want; and it is to be hoped also that, by multiplying or extending their scope, they will prove not only of additional benefit to intending physicists, but also to ordinary students, by ridding the vulgar treatises, and eventually lecture courses, of much superfluous matter that acts as a serious incumbrance and impediment to the spread of *real* physical science.

Prof. Kohlrausch's little book, of scarcely more than one hundred pages, reproduces, or very nearly so, the practical *curriculum* familiar to those who, in former time, attended at Göttingen the exercises which Profs. Weber and Listing superintended there for many years. The subjects selected range over a considerable field, and include a variety of problems; but the work was not intended to be exhaustive. Common weighing, specific weights and densities, thermometry, magnetism and galvanism, and optical instruments, furnish the chief topics on which exercises are indicated. Of course, the work is not designed to be read by itself, but to serve as a manual of instruction in the practical execution of the several processes. Nor should it be thought that even practical work of the kind here indicated can serve as a training for future discoveries, any more than early verse exercises make any one a poet; it completes, and familiarises with, the knowledge of discovered truths, but does not teach the discovery of truth. Original research of high value can be made as little on the pattern or with shreds of old, as genuine poetry can be composed in imitation and with patches borrowed from the ancients. Scientific investigation is a work of inspiration, and if directed towards a new aim, requires also novel instruments and new procedures. Chemical operations proper possess, it is true, a considerable degree of uniformity, and are capable of methodical treatment and exposition; but physical processes and manipulations are multiform, numerous, and difficult to classify. This is the reason why physical laboratories are as yet few and far between, and none of them so systematically organised as the chemical laboratories; and that, while the workers in

* *Leitfaden der Praktischen Physik.* Von F. Kohlrausch. (Leipzig, 1870.)

* L'Art des Expériences. † Cabinet de Physique.

Chemistry surpass in numbers, they also outdo in individual productiveness, the workers in Physics. But since the institution of physical laboratories is nevertheless spreading, the very novelty of their existence makes the publication of books like that of Prof. Kohlrausch, proceeding from older establishments, a real boon to those called upon to superintend or take a share in the direction of the practical work of new ones; and it is only to be hoped that from other places of renown also, both in England and abroad, similar publications may also soon proceed. C. K. AKIN

GALLOWAY'S QUALITATIVE ANALYSIS

Manual of Qualitative Analysis. By Robert Galloway, F.C.S. Fifth edition, xxi. and 415 pp. (London: John Churchill and Sons.)

OF the various manuals of Qualitative Analysis now in use, none is more deservedly popular than the work of Professor Galloway. Much of this success is doubtless due to the painstaking care with which the author has sought in successive editions to reduce the operations of Qualitative Analysis to a more methodical and systematic process. The present edition is in great part rewritten, and much new and original matter has been incorporated. More systematic methods for separating the alkaloids are given, together with many additional reactions for their individual discrimination. The processes for detecting the poisonous metals in presence of organic matters are also much improved. A description of Bunsen's neat and expeditious flame reactions is likewise a new feature in the book. The delicacy and certainty of these reactions ought undoubtedly to lead to their more general adoption in our laboratories; even if their application is found to be limited, the lesson in neatness and dexterity in working to be acquired in their performance would prove invaluable to the student.

One of the characteristics of this book is its thoroughness, and the very example of this quality will not be lost upon the beginner. As an illustration of what we mean, we give the following extract from the introductory remarks on the province and scope of qualitative analysis:

> The analyst, by means of re-agents, interrogates the substance to be analysed as to what are its component parts; the reactions are the language in which the answer is returned. The student has therefore to learn the mode of questioning the substance, and the language in which the answer will be conveyed; in other words, he has to learn, not only what general and special re-agents are to be employed, but the order in which they are to be applied, and also the reactions they produce with the bases and acid-radicals, before he can attempt to search for these bodies in substances. No amount of *reading or lecture-hearing* will furnish the student with this knowledge; he can only obtain it by making the experiments himself of the different bases and acid-radicals with the re-agents, and "*he must always reflect, before the addition of the re-agent, for what purpose he applies it, and what are the phenomena he intends to produce.*" And the conditions indispensable for the production of correct and decisive reactions must be carefully observed, for a half-knowledge in all departments of science is of little worth, but in chemical analysis it is worse than useless.

There must always be diversity of opinion respecting the best method of teaching Qualitative Analysis, or indeed of teaching any branch of practical science; since so much depends upon the qualifications and conscientiousness of the teacher. In the Preface to the present edition of his book, Professor Galloway makes some very pertinent observations respecting the advantages which the method he adopts possesses over that employed by Fresenius and in the Giessen Outlines. It is quite possible that by faithfully following the plan laid down by the German professor, the student may succeed in correctly determining a larger proportion of the mixtures given to him for analysis, and yet the amount of actual benefit which may accrue to him may be far less than if he were more frequently unsuccessful by working under a system which left more to his individual judgment and intelligence. We believe that the method of Fresenius, as an educational agent, is radically bad; its tendency is to make the learner degenerate into a mere analytical machine. Such a system (to employ the phraseology of Mr. Galloway), of simply *telling* this and *showing* that, may be most pernicious in its consequences. The chief object in teaching chemistry is thus too frequently missed; science so studied renders the student utterly incapable of correctly reasoning upon the knowledge he acquires, for merely to create a number of proficient analysts is not the primary end of the introduction of qualitative analysis into the *curriculum* of our schools and colleges. A perfect system, then, is that which, whilst employing the most satisfactory and expeditious analytical methods, yet allows sufficient latitude for the student to exercise and strengthen the powers of his originality, reason, and intelligence. Such a system Professor Galloway has attempted to frame, and we have no hesitation in asserting that in the hands of a conscientious student his book will lead to the result which he desires to obtain. T. E. THORPE

WORKS IN NATURAL HISTORY

Works in Natural History, &c. By the Rev. F. O. Morris, B.A.

THIS is, in several respects, a very remarkable pamphlet. It shows us, to our great gratification, that the study of Natural History is, thanks to the labours of Mr. Morris, gradually finding its way into Royal Palaces and Baronial Halls, for we learn that Her Most Gracious Majesty the Queen has accepted the dedication of his "History of British Birds;" that his Excellency the Right Honourable the Earl of Carlisle, K.G, &c. &c., influenced probably by Her Majesty's example, has extended his patronage in a similar manner to the "Natural History of the Nests and Eggs of British Birds;" that his "British Butterflies" and "British Moths" are under the genial and aristocratic guardianship of the Honourable Mrs. Musgrave and the Right Hon. Lady Muncaster; that his "Anecdotes in Natural History," and "Records of Animal Sagacity and Character," are dedicated by permission to the Most Hon. the Marquis of Westminster, K.G. and the Hon. Anne Emma Cavendish; while His Grace the Archbishop of York stands sponsor to "The Difficulties of Darwinism." Surely even in the so-called Golden Age of English literature, no author could have had the good fortune to secure so many noble patrons.

Appended to the title of each of Mr. Morris's works are "Notices of the Press," and in this department the compiler of the pamphlet would, we think, have acted more wisely and more in accordance with the dignity of

Science, if he had restricted himself to journals, reviews, &c., of acknowledged literary merit, or treating specially of Natural History. Who, with a grain of common sense, cares to know, or attaches a shade of value to, the scientific opinions of such periodicals as the *Doncaster Gazette*, the *York Herald*, the *Derbyshire Advertiser*, the *Yorkshire Gazette*, the *Worcester Journal*, the *Bromsgrove Messenger*, the *Yorkshire Post*, *Our Own Fireside*, the *Oriental Budget*, the *Threepenny Magazine*, the *Penny Post*, the *Rock*, or the *Record?* This kind of puffing (for we can find no other term to express our meaning plainly) is bad enough; but there is worse, far worse, to come. It surely cannot have been with the knowledge and concurrence of "The Rev. F. O. Morris, B.A., Rector of Nunburnholme, in this county, and Chaplain to his Grace the Duke of Cleveland," as he is designated in the *York Herald*, that a series of anonymous opinions on his "Difficulties of Darwinism"—many of them abounding in the most gross and fulsome flattery of himself, and in vulgar abuse of his opponents—have been appended to the more legitimate notices of that book. Lest we should be supposed to be using unnecessarily strong language, we shall quote a few of these precious criticisms:—

"Professor Huxley's letter to you is in his usual style—flippant and rude. Your reply is in every way admirable. —Professor ——."

"I have read your pamphlet, and do not see how it can be answered.— ——Esq. M.D., A.B."

"Prof. Huxley's impertinent letter *deserved* what it has *got*. You certainly have given him a castigation.—Rev. ——, Cantab."

"The papers here steer shy of your pamphlet. They are on the other side, and find it awkward to reply to. I am very glad to hear that you purpose meeting Huxley at Liverpool. He requires a man that can expose his shuffles, and turn his banter against himself.—Rev. ——, D.D."

"Glad to see you an opposer to Darwin's nonsense.—, ——, Esq."

The last of these absurdities is apparently a round-robin printed in a straight line: "We agree with all you say most perfectly. We cannot imagine how it can be answered by the Darwinites." Then follow three dashes.

Mr. Morris is not merely a well-educated English gentleman, but a clergyman and chaplain to a duke; and we feel that we are doing him a service in giving him an opportunity of stating (1) whether these extracts are really taken from letters addressed to himself, or whether they are forgeries; and, (2) in the former case, of explaining how they found their way into print in this obnoxious form.

A geological friend of ours, while trying to make a short cut, trespassed on a railway line. He had not gone far before he was stopped, and told by a grim official to retrace his steps. Our friend, thinking that a little "soft sawder" might help him out of the difficulty, observed: "My good fellow, you are perfectly right, and are only doing your duty; but I am much mistaken, when I look at your kindly and good-natured face, if you are the sort of man to turn a harmless geologist a couple of miles out of his route." The heart of the guardian of the road was so far softened by this speech as to let our friend proceed rejoicing, but, as a parting shot, he observed:—"Well, sir, I *do* like a bit of butter, but I ain't partial to grease." Now, to apply this anecdote, we sadly fear that Mr. Morris is "partial to grease." Many clergymen indulge in this taste, and one who has associated so much as this distinguished naturalist has done with the *Dii Majores* is apt to grow unctuous. On the assumption that these extracts are genuine, we can fancy that he carried the parcel of letters in his coat-tail pocket when visiting his parishioners, and occasionally sat down to enjoy a bit of grease, or, in other words, to read one or two extracts, as a cheerful mental stimulant; that probably on one occasion, the stimulant was too much for him, and that he inadvertently left the packet "*sub tegmine fagi;*" and that an enemy (probably a rabid Dissenting minister of a low class) picked up the prize, at once saw its value as a weapon against the Church of England, and gave it up to the Elders of his congregation, on the condition that they should publish it. It was then probably placed in the hands of a literary gentleman—possibly the Editor of the *Threepenny Magazine* or the *Penny Post*—and thus, and thus only, the appearance of the pamphlet can, we think, be rationally accounted for.

OUR BOOK SHELF

Resources of the Southern Fields and Forests, Medical Economical, and Agricultural. By Francis Peyre Porcher, M.D. (Charleston: 1869.)

In this book we have very full accounts of the uses of the plants of the Southern States of America. The author freely acknowledges in his Preface (or, as it is here termed, "Preliminary,') that he has availed himself largely of numerous works on kindred subjects, most of which have been published in America. In the introduction a few practical instructions are given for collecting and drying medicinal products of the vegetable kingdom. The plants are arranged according to their natural orders, the vernacular names being placed first, followed by the scientific names, and the distribution of the plants in the States. No attempt is made either at a scientific or popular description of the plants themselves; so that the book is literally what it professes to be, without being made bulky with matter that can, if required, be found in floras or purely botanical works. The book, indeed, is written more with an eye to the exposition of the medicinal uses of the plants; but the "economical and agricultural" portion is by no means lightly treated. In short, the information is most varied, as will be seen from a few quotations. Here is a recipe for making blacking from elder-berries, certainly an application we never before heard of:—"Boil elder-berries well, mashing the pulpy matter; then strain through a colander, and bottle for use. The liquid sours somewhat by age, but retains its qualities. Another way is to simmer ripe elder-berries over a slow fire in an iron kettle for one hour and let the mass cool, and you will have good blacking." Under the head of White Beech (*Fagus sylvatica*, and *F. americana*) our author tells us "the leaves of the beech trees, collected in autumn in dry weather, form an admirable article for filling beds. The smell is grateful and wholesome, they do not harbour vermin, are very elastic, and may be replenished annually without cost." There is nothing new in this application of beech leaves; they are used in many parts of Europe for a similar purpose, and were at one time so employed in England. Evelyn speaks of them as affording "the best and easiest mattress in the world to lay under our quilts instead of straw;" and by way of recommendation says that "divers persons of quality in Dauphiny" use them. The above are examples of what may be called purely economical applications. We take a cruciferous plant, the Gold of Pleasure, or False Flax

(*Camelina sativa*) as a single example of agricultural produce. "The cultivation of this plant for the seed would repay the farmer; an abundance of chaff would be produced which would be of infinite service for horses or for manure. In a grazing country like England, where vast sums are annually expended for foreign oil-cake, the Gold of Pleasure will soon be found an excellent substitute under manufacture, and, consequently, a grower should find a good remuneration in cultivating the seed. The oil-cake has been found highly nutritious in the fattening of sheep and oxen, as it contains a great portion of mucilage and nitrogenous matter, which combined are found very beneficial in developing fat and lean." The prospects of making this a most important agricultural plant are, we think, too brightly drawn, considering that it has not escaped the notice of English agriculturists. Neverthless, a few words of this kind on different products might help to promote experiments on their culture and utility. The writer's aim throughout seems to be a general utilisation of vegetable productions, and he very ingeniously finds a variety of application for those of the Southern States. We do not hesitate to say that a few books of this description on the economic products of different parts of the globe, would make us much better acquainted with the true value of the vegetable kingdom than we are at present. JOHN R. JACKSON

Adventures of a Young Naturalist. By Lucien Biart. Edited and adapted by Parker Gillmore. (London: S. Low, Son, and Marston, 1870.)

THIS is a narrative of travel in Mexico, intended especially for young people interested in Natural History. The party consists of a young lad the hero, his father, a Swiss naturalist who does all the moralising, a dog, and one of those half-bred Indians who know everything and can do everything, who are such a bore in most books of Western travel. Though written in a somewhat pedantic style, we have no doubt it will find many admirers among our adventure-loving young readers, the country described being one of unsurpassed beauty and interest. For our own part, we should decidedly object to being cross-examined in the following manner before being allowed to eat our breakfast. "Do you know the family of the animal we are going to have for breakfast?" asked Sumichrast. "Yes; it is a Rodent." "Well done; but how did you recognise it to be so?" "By the absence of canine teeth in its jaws, its large incisors, and its hind-legs being longer than its fore-legs." Especially if the lesson were given in such a confused style as this:—"The bird belongs to the family of Climbers, that is to say, to that order which have two toes in front of their claws and two behind, like your great friends the parrots." Still the young naturalist will find in the book much that is interesting and amusing; and the numerous illustrations and gorgeous binding will make it an acceptable present during the Christmas season.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Contribution to the Dioptrics of Vision

IN the course of some experiments in reference to vision under water, I have ascertained some facts which I do not remember to have seen mentioned by writers on optics, and which may perhaps interest your readers.

Every swimmer knows that, however clear the water may be, and however distinctly he may see from the bank the smallest particle of gravel or weed, the moment he plunges beneath the water all becomes obscure, and he can see the outline of nothing at the bottom or suspended in the water distinctly, but only blurred patches of various colours. In my first endeavours to find a remedy for this imperfect vision, I found two ways of restoring perfect sight. The one was to surround the eye with a watertight box, with a piece of plain glass in front. By this means, the eye being in the same condition as to receiving the rays of light through an aërial medium as when we are on land, perfect vision is retained beneath the water. The other was, allowing the eye to remain exposed to the water, to look through a glass lens whose proper focal distance in the air, I found, after numerous trials, to be half an inch. The first method is attended by the disadvantages that the glass soon becomes dim from the condensation of vapour, and it is difficult to make it fit so accurately as to exclude the water; the second is more convenient, as any optician can construct a pair of spectacles suitable for the water, and fitted with lenses of the required focal distance.

Fishes, cetaceous animals, and seals, see perfectly below the water, while man's vision, unassisted, is of the most imperfect character. The eyes of these marine animals differ from those of terrestrial vertebrates chiefly in this: the latter have a very convex cornea, with a large chamber containing aqueous humour and a double convex lens behind; whereas the former have a flat cornea, hardly any aqueous humour, and a spherical lens, lying, at least in fishes, close behind the transparent membrane which is their substitute for a cornea.

Now, as an optical instrument, the eye of terrestrial vertebrates—and let us take that of man for an illustration—consists of two lenses, one placed behind the other. The anterior lens is formed by the aqueous humour, its actual figure being a meniscus, one surface being convex the other concave, but both surfaces uniting if prolonged. According to Donders, the anterior radius of curvature, formed by the cornea, is 8 mm., the posterior, formed by the front of the crystalline, being 10 mm. The posterior lens is the crystalline, a double convex lens, its posterior surface, according to the same authority, having a radius of 6 mm. only. The combination of meniscus and double convex lens is known to possess peculiar optical advantages. The vitreous humour cannot act as a convex lens, its form being that of the concavo-convex lens, whose property is to cause divergence of rays of light; but, as it lies in contact with the retina, it cannot even produce this effect. It acts, together with the aqueous humour, as a watery medium for the suspension of the crystalline.

What happens when the human eye is immersed in water? A transparent lens-shaped body will refract the light in converging rays, if it is much denser than the surrounding medium through which the rays of light reach it. A simple experiment will prove this. Take two watch-glasses with their concavities facing one another; fill the space between them with water; this will form in air, than which it is so much denser, a lens of power proportioned to the convexity, but in water it will not refract the light at all, being of the same density as the light-conducting medium. The aqueous humour of the eye being much denser than the air, acts as a lens in the atmosphere, but being of the same density as water, when the light is transmitted to it through water in contact with the eye, we at once lose the use of our anterior lens, and can see nothing distinctly; because the crystalline, which alone now acts as a lens, throws its focus, as we shall presently see, beyond the retina.

How, then, are we to recover perfect vision under water? Obviously, by supplying the loss of our anterior lens by another lens of equal power. The focal distance in the air of a water lens of the meniscus shape and the dimensions given above may be calculated; it is, in fact, two inches or thereabouts; but, as we have seen, it $= 0$ in water. But, as the refractive power of a lens diminishes in proportion as that of the medium through which it receives rays of light increases, we find that a glass lens when immersed in water has only one-fourth of the refractive power it possesses in air. So, in order to supply the loss of our anterior lens, we find we must use a glass lens of about half an inch focus, which, in water, has a focus of about two inches. I need scarcely say, that in the case of a double convex lens of dissimilar curves it makes a great difference as regards the refractive power whether the lens be wholly immersed in water or one or other of the convex surfaces only. But I need not dwell on this subject at present.

But it is a clumsy method to supply the loss of a lens of two inches focus by one of the high refracting power of half an inch. Besides, a glass lens of this power is so small that the lateral field of vision is of necessity very limited, and it has a further disadvantage that we can see nothing with it in the air. I therefore sought for a lens that should be free from these defects.

As the ocular lens whose place had to be supplied is formed of water, and receives in the normal condition the rays of light through air, I thought I might make my subaqueous lens of the same media. A couple of watch-glasses, placed with their concavities towards one another, so as to enclose a convex lenticular portion of air, when immersed in water, disperse the rays of light and diminish the size of objects seen through them, because they force the more refractive medium, the water, to assume a *concave* shape in relation to the air between the glasses. The same watch-glasses placed with their convex surfaces towards one-another, and connected round their edges by a water-tight rim, thus enclosing a concave lenticular portion of air, when immersed in water, refract the rays of light convergently to a focus and magnify objects, because they force the more refractive medium to assume a *convex* shape in relation to the air between the glasses. Their magnifying power or focal distance under water is somewhat less than that of the same glasses in the reversed position and filled with water is in air; the slight difference being owing to the greater refractive power of the glass in air than in water. I found that two glasses of a curvature of about $1\frac{1}{4}$ inch radius thus placed formed in water a lens having a focus of about two inches. This *air-lens*, as it may be called, completely supplies the loss of our anterior lens in water, and restores perfect vision. Of course the same magnifying power may be obtained by various combinations of differently curved glasses, or by plano-concave or concavo-convex air-lenses. The advantages of this kind of lens for subaqueous vision over a glass lens are obvious. It can be made of any required size so as to command a large lateral field of vision. It ceases to act as a lens the instant it emerges from the water, and does not interfere with vision in the air, as then we merely look through two thin pieces of glass with some air between them. There is no provoking loss of refractive power, as in the case of the glass lens; and lastly, it can be made very cheaply. With either form of lens we can see from below the water objects in the air above us quite distinctly if the surface of the water is smooth, less distinctly if it is agitated.

Air lenses constructed on the principle described may be made of any magnifying power, and are much better adapted for the microscopic examination of objects under water than glass lenses, whose refracting and magnifying power is reduced to one-fourth by immersion. Thus a glass lens of a quarter-inch focus in air, would scarcely be equal in water to an air lens of one inch focus.

I have said that the difference between the refractive power of a glass lens in air and water is as 4 to 1, or even more. The difference is about the same in the case of the crystalline. Thus, the spherical lens of a cod, which has a focus of about $\frac{3}{20}$ of an inch in air, has a focus of about $\frac{3}{5}$ of an inch in water, which is about the distance of its posterior surface from the retina in the fish. Supposing the focal distance of the human crystalline to be, in air, $\frac{1}{5}$ of an inch, it will be more than $\frac{2}{3}$ of an inch in the fluid in which it floats. But, in front of it, we find what I have called the anterior lens—I mean the aqueous humour—with a focus, as I have proved, of about 2 inches. If we take two lenses respectively of 2 inches and $\frac{2}{3}$ of an inch focus, and place the weaker over the stronger, we shall find their united focal distance to be about $\frac{1}{2}$ an inch, or about the distance between the back of the human crystalline and the retina. My measurements, in the absence of appropriate instruments, lay no claim to exactness; they are, however, a sufficient approximation to truth for my present purpose.

How is it that after the operation of extraction of the crystalline lens, which has a focus of less than 1 inch in its natural position, the patient can see distinctly with a lens of from 3 to 4 inches focus? The reason seems to be that the optical character of the eye is completely altered by the operation. The space formerly occupied by the crystalline is now filled with aqueous and vitreous humour, and the eye represents a sphere of water, bulging in front into a more convex form by means of the cornea, which will have the effect of a superimposed meniscus of about 2 or $2\frac{1}{2}$ inches focus. A thin glass sphere filled with water of 1 inch diameter will roughly represent the eye deprived of its crystalline. We find the focus of this sphere to be about $\frac{1}{2}$ an inch. Let us place in front of it a lens of $2\frac{1}{2}$ inches focus to represent the bulging cornea, and we find the focal distance diminished by more than one-half. Another lens of 3 to 4 inches focus will bring this focus close to the posterior surface of the sphere, in fact, to the situation of the retina in the actual eye. This explains what happens in the eye deprived of its crystalline. Such an eye will require a much more powerful lens for subaqueous vision than that above described.

Montagu Square R. E. DUDGEON, M.D.

Dr. Lankester and the Scarlet Fever Epidemic

PERMIT me to make a few remarks on some notices of my paper on scarlet fever, published in your pages on the 17th of November last. Referring to my recommendation as to the destruction of the poison of scarlet fever, the *Pall Mall Gazette* says—"All this is very well in its way, and may be carried out by the upper and middle classes, among whom the mortality from scarlet fever is comparatively small; but the plan is quite out of the reach of poor creatures who have but one room, one bed, and one suit of clothing, which even at night takes the place of blankets." My object in writing the paper was to show that scarlet fever might be averted by certain measures, and I left it to those who read it to devise the means of making them available for all. When the cattle disease broke out, an Act of Parliament was passed for the purpose of diverting it. The lives of human beings are surely of not less value even in a money point of view than those of cows and oxen, and I have the conviction that certain measures might be adopted by the Government that would reach even the "poor creatures" to whom the *Pall Mall Gazette* alludes. Even now there exist Acts of Parliament which, if at once put in force by boards of guardians, town councils, vestries, and other local authorities, would at once enable them to put down this disease. The inhabitants in "one room, one bed, and one suit of clothing," are reached by medical men, and they might be empowered to remove the sick from the healthy, to destroy useless infected clothing, to have the infected linen washed, and generally to see that the disease is arrested. What can be done amongst the rich ought to be done amongst the poor, and expense ought not to be allowed to stand in the way of such merciful measures. It should be remembered that such outlay on the part of wealthy ratepayers would, in the end, repay them, as they catch this disease from its being fomented among the poor, and they would no longer be liable to these attacks when their less opulent neighbours were free from them.

In the pages of the *Lancet* "A General Practitioner" states that I have reflected on the members of the medical profession in stating that they do not exert themselves to suppress this disease. I spoke from a rather extensive experience on this subject, and regret to say that I have nothing to withdraw on this point. I did not say it was the fault of medical men. I said they were not instructed. This is the fault of a system of medical education in which public health is not contemplated as a part of its course It is true that within the last two or three years chairs of Hygiene have been established at University and King's Colleges, London, but these are exceptional. So deficient is the education of medical men on this very point, that the Government felt itself justified in opening a special medical school at Netley for the purpose of supplementing the defects of our ordinary medical schools. It is from the Chair of Hygiene at the Military Hospital that the most admirable work on Hygiene in our language, by Dr. Parks, has issued.

"A General Practitioner" could not suppose that I was ignorant of the fact that all that has been done for our knowledge of the nature of contagious diseases had been done by medical men, and that our medical officers of health have especially exerted themselves in endeavouring to prevent the spread of contagion. I must, however, again express my surprise at the small amount of information that can be gained from the text-books on the practice of medicine as to how best to prevent the spread of contagious diseases.

I will not in your pages do more than allude to the offensive tone and expressions of "A General Practitioner," but I may add that no amount of "support" I may have had or may expect to derive from members of my profession, will ever induce me to refrain from speaking the truth of them in the interests of the public. I am, however, fully convinced that it is only by such a course that I can hope to retain the respect and continued "support" of the more intelligent and honourable members of my profession. EDWIN LANKESTER

Professor Tait on Bain's Logic

IN your last week's number, Prof. Tait publishes a portion of his Introductory Lecture to his class, in which he criticises certain passages in my work on Logic, having reference to the doctrine of the Conservation of Force. Although I do not, in every instance, admit the justice of the strong condemnatory phrases used in the criticism, I am aware of having committed a mistake in stating the relation of Momentum to Energy or *vis viva*, and will endeavour to rectify it.

In quoting a dictum of the late Dr. Boole, Prof. Tait styles him the greatest logician the world has produced, or is likely to produce, for many a long day. In dissenting from this superlative, I do not refer to the men most widely known in recent years as logicians—Whately, Hamilton, Mill, Mansel; I consider that the comparison of them with Boole fails through the dissimilarity of the matters compared; his Logic was but to a very small extent the Logic of any one of these writers. The only person who cultivated Logic in the manner of Boole was another noted mathematician, the veteran De Morgan. Now, without undertaking to say which of these two had the greater genius, I do not scruple to affirm that the labours of De Morgan, in their common department, if only through longer continuance in time, resulted in a much larger number of contributions to the science than can be credited to Boole. The two men were friendly co-operators, not rivals; and they will, I have no doubt, be mentioned together as often as reference is made to the Algebraic extensions of Formal Logic.

The Spectrum of the Aurora

THE brilliant displays of the Aurora Borealis observed in England on the 24th of September and the 14th of October, 1870,* were also generally observed in this country. The fact may be worthy of record in your journal, as indicating the unusual extent of the phenomena. As the newspapers in different parts of the United States contained full descriptions of these displays, a detailed account need not here be given. I may remark, however, that they were generally regarded as the most brilliant displays we have had since 1859. Fine auroras were again witnessed on Monday morning, October 24th, from 5 to 6.30 A.M., and on the evening of the same day, from 6 to 11 P.M. At 9 P.M. (on the evening of the 24th) an auroral arch passed very nearly through the zenith from the eastern to the western horizon, or rather from a point a few degrees south of east, to another somewhat north of west. An extraordinary number of more feeble auroras have been noticed during the last two months. DANIEL KIRKWOOD

Bloomington, Indiana, Nov. 9

Can Aurora be Seen in Daylight?

I VENTURE to believe *not*, in spite of circumstantial accounts to the contrary, and I ground my belief on the following considerations:—1. No description of a daylight aurora that I have ever seen will bear a critical examination. Take that published in the last number of NATURE. Here two arcs of faint white lines are said to have been seen in a direction "almost due east," and certainly the illustration given is not very unlike the appearance that auroral arcs sometimes present. But auroral arcs, so far as I know, never appear in the east, and the conclusion, therefore, is unavoidable that the object observed was nothing more than a remarkably symmetrical form of cirrus cloud. In another instance, lately published, although the thing described is called a daylight aurora, I fail to see in the description anything more than an account of the appearances presented when a high canopy of cloud clears off bodily from the sky with a sharp, straight edge, which by perspective becomes an arch. In the case referred to, the clouds clearing off from the direction of magnetic north, the arch corresponded in position with that of an aurora, and hence was set down as auroral. In a third account of a daylight aurora, it is expressly mentioned that the sky was hazy, and a solar halo visible, a condition of things which, while it would make the occurrence of aurora-like cirrus extremely probable, would be specially unfavourable to the visibility of a true aurora; for certainly if so delicate and phosphorescent a light as that of an aurora is to be seen at all in the daytime, it can only be under circumstances the most favourable as regards clearness of the lower atmosphere.

2. A comparison of the auroral light with the light of other objects whose visibility can be more easily measured, tends strongly to confirm the view I have advanced. No one who remembers Donati's comet at its brightest will hesitate to allow that for intrinsic brilliancy that object surpassed the most vivid aurora. Yet Donati's comet at its brightest could not be detected with the naked eye until about half an hour after sunset, and then only the head could be seen.

3. The modifications of cirrus cloud are so infinitely diversified, and sometimes so very remarkable, as to offer a great temptation to the observer to invest them with the mysterious attributes of the aurora. Moreover, they do occasionally present a very striking resemblance to pencils of auroral light, differing, however, essentially in the character of fixity which they possess, as well as in the absence of any determinate relation to the magnetic pole or zenith.

On the grounds now stated I venture to refer daylight auroras in general to the large class of "errors of observation."

The North London Naturalists' Club

THE Secretary of the North London Naturalists' Club desires the Editor of NATURE to correct an incorrect statement which appeared in the last number of that journal. The North London Naturalists' Club is not broken up, it is not six years old, nor has it ever met on a Monday. Its last meeting was on Thursday, Nov. 24, at Myddelton Hall. Three subjects were then exhibited and explained, viz. "The Structure and Growth of the Yeast Plant," "The Structure of the Gastric Teeth in the Lobster," and "The Anatomy of Amphioxus." The meeting was thinly attended, but that is no alarming phenomenon for societies of this kind. The previous meeting on Oct. 27 was a very full one, owing to a paper read by a deservedly well-known member of the club on the highly interesting subject of "Spontaneous Generation." It must be confessed that the club is not so vigorous as when first started, but these facts show that it is by no means defunct. J. SLADE,

Hon. Sec. N.L.N.C.

Browning's Spectroscope

IN the last number of NATURE there is a description by Prof. Young of a spectroscope, in which the prisms are made to alter their positions relatively to each other by bending backwards and forwards the metal work to which they are attached. I should of course not wish to offer any opinion on the efficiency or otherwise of this arrangement.

My reason for writing is that in the course of the article Prof. Young goes out of his way to remark that, in attaching bars at right angles to the bases of the prisms in my Automatic Spectroscope, I have adopted a plan of Mr. Rutherford's. Will you kindly permit me to state that I began my Automatic Spectroscope in the year 1862, and that, so far as publication consists in exhibiting anything to a large number of persons, I had published it in the year 1863. I have reason to believe that M. Duboscq also attached bars in a similar manner to the bases of prisms with the intention of obtaining a minimum deviation adjustment, about the same time as myself, or soon afterwards. I do not know at what time Mr. Rutherford may have contrived his plan, but, as I have never read any description of his instrument, I must disavow having adopted any plan of his. At the same time I must remark that it is a small step towards obtaining the complicated movement required to produce an *automatic* minimum deviation adjustment, and it seems to me that it is a step every person would be likely to take who wished to obtain the adjustment by a mechanical motion.

111, Minories, Dec. 12 JOHN BROWNING

Evolution of Light

YOUR correspondent, who describes in the number of NATURE of the 17th ult. a faint light observed by him on tearing strips from a woven fabric in the dark, may be interested to know that a similar phenomenon is noticed by Mr. Grove in his "Correlation of Physical Forces," as occurring with indiarubber waterproof cloth (4th ed. p. 48).

Mr. Grove ranks it under phenomena of heat and light, rather than of electricity. C. J. T.

Fungi

IT is very unfair that the mushroom amily should lie under a ban, because Locusta, at the instigation of Agrippina, employed some kind as a medium for conveying poison into the stomach of Claudius. With equal justice the mild Calenian wine would have been in ill repute because poison was not unfrequently mixed with it—

> Occurrit matrona potens. quæ molle Calenum
> Porrectura viro miscet sitiente rubetam.

I cannot therefore think that the bad name clinging to the whole family of agarics was thus incurred; for Locusta did not employ a poisonous fungus for her deadly purpose: she mixed poison with some kind of mushroom of which Claudius was particularly fond, and of which he had no doubt often partaken. The words of Tacitus are explicit; he says that "the writers of those times have related that poison was poured into a dish of *boleti*, of which the Emperor was fond;" "Temporum illorum scriptores prodiderint infusum delectabili cibo boletorum venenum." (An. xii. 66.) Suetonius is equally clear: "Boletos in quo cibi genere venenum acceperat." (Nero 33.) Pliny, too, seems to regard the boleti, which he calls an excellent food, as the vehicle conveying the poison: "Veneno Tiberio Claudio principi per hanc occasionem a conjuge Agrippina dato." (Nat. Hist. xxii. 22.) Cases of accidental poisoning by fungi no doubt occasionally happened amongst the ancients as amongst ourselves, but I doubt whether any of the family of fungi were ever designedly employed as a poison. According to Pliny, Annæus Serenus, the prefect of Nero's guard, with his tribunes and centurions, accidentally met their death by eating some poisonous fungus; I am not aware that any other writer records the circumstance; it is rather curious that Seneca, a very dear and intimate friend of Serenus, makes no allusion to the cause of his friend's death, in his touching lament over it, when we remember the philosopher's intense aversion to the fungus tribe. Here is a specimen of his vigorous diatribe: "Good gods! how many men does one belly engage! What! Do you think that those boleti—a pleasant poison—albeit they hurt not now, conceal within them no hidden mischief?" (Ep. xcv.) In another place (Ep. cviii.) he speaks of boleti and oysters together as things he had for ever renounced: "For they are not food, they serve only to tickle the appetite, constraining those that are full to eat more; a very gratifying amusement to such persons as stuff themselves with such things as readily go down, and as readily return." The *boletus* instrumental in causing Claudius's death has been supposed to be the *Amanita cæsarea*, the specific name being given to this fungus on that account, but the point cannot be decided. That the genus *Amanita* was known to Pliny appears pretty evident from his description: it is first covered by a volva, egg-like, and then it breaks through this and rises on its stem. I can find no distinctive mention of the tubes or pores, characteristic of the order Polyporei, in any classical author. The *boletus* of the ancients might have included the modern genus Boletus and some of the Agaricini. Some of the Polyporei are no doubt denoted by the *μύκητες ἀπὸ τῶν ῥιζῶν καὶ παρὰ τὰς ῥίζας φυόμενοι* of Theophrastus (iii. 7, § 6); and Pliny probably means the same when he speaks of fungi growing on trees. Whatever the boleti were, they were highly esteemed; we find them not unfrequently contrasted with *fungi* and *suilli*:—

> Vilibus ancipites fungi ponentur amicis,
> Boletus domino. (Juv. *Sat.* v. 146.)

Compare also Martial (iii. 60):

> Sunt tibi boleti; fungos ego sumo suillos.

Boleti were so good that you could not trust a slave to convey them to a friend; he would be sure to eat them on the way:—

> Argentum atque aurum facile est, lænamque togamque
> Mittere: boletos mittere difficile est. (xiii. 48.)

What the kind known as *suilli*, "hog-fungi," were, cannot be determined.

W. HOUGHTON

Hereditary Deformities

THE facts about hereditary epilepsy in guinea-pigs, mentioned in NATURE of 3rd ult., on page 14, appear to show that mutilations may be inherited when accompanied by functional derangements; though there appears to be very little, if any, evidence of mutilation being inherited when not so accompanied.

Dr. Carpenter says somewhere (I cannot find the reference) that small scars are sometimes more persistent than large ones. We might consequently expect that they would be liable to become hereditary. But this does not appear to be the fact. To mention an obvious instance: in many countries, the ears of all the girls, and of many of the boys, are pierced for earrings. We could not expect to find the perforation hereditary, but it would not be wonderful if the external scar were to be so; the smallness of the operation, not amounting to mutilation, and not producing any functional disturbance, might be thought to be in favour of this result. But I am not aware that it is ever found.

The Colour of Feathers and of Butterflies' Wings

THE change of colour observed by E. V. F. (NATURE, No. 55) in the red parts of the wing of a butterfly by the application of muriatic acid, is in all probability due to the red colouring containing a trace of copper in its composition. I have demonstrated the almost universal presence of that metal in the sea, in the earth, in fish, in flesh, in vegetables.

Not long ago Professor Church showed it to exist in the red feathers of birds.

Man's Bare Back

WILL you be good enough to favour me with a small space in your excellent journal for these few lines, in answer to Mr Wallace's difficulty with regard to the nudity of the back of man. According to Darwinian principles, there is what is called correlation of growth, by which I believe is meant, that an organ, or some part of the organism, is selected, not because itself is useful, but because its growth is somehow correlated to some other organ which is useful. Now, as a growth is admitted which exists by virtue of its correlation to some useful organ, why should not an atrophy of some part of the organism also be admitted as correlated to some organ which has been naturally selected on account of its usefulness? Although the nudity of the back of man is not in itself useful, nevertheless the atrophy of the hair on his back may be correlated to the development of some organ peculiar to man, and which is useful to him; or, in other words, the growth of the hair on the human back, although in itself useful, is incompatible with the growth of some other organ which may be infinitely more useful to him. Such atrophy, for all we know to the contrary, may be in some way correlated to cerebral development, to the erect posture, to the development of the hand, to the organs of speech, &c. At all events, if we cannot positively state that our dorsal nudity is so correlated, we certainly cannot say that it is not. I do not think that Mr. Wallace is justified in excluding the nudity of the back of man from the theory of natural selection, because he cannot show that it is useful. It may not in itself be useful, but it may be subordinate to some organ which is most useful. I consider that if the principles of a correlated atrophy be admitted, the stumblingblock of our bare backs will cease to trouble Darwinian thinkers. The argument struck me when I first read Mr. Wallace's remarkable "Contributions to Natural Selection," but as I now see, by his article in p. 9, No. 53, Vol. III. of NATURE, that his difficulty has not been answered, I venture to address the foregoing to you, with the hope that my argument may be of some utility.

Loss of Temperature in Climbing

FREQUENT reference has been lately made to the thermometrical results obtained by Dr. Lortet while walking up Mont Blanc, in which, as stated by Dr. Corfield in NATURE of Dec. 1, his temperature fell about 4° C. in ascending nearly 4,000 metres. Mr. E. R. Lankester informs me that when undertaking the same journey, he also found his temperature much lower when he was up high than when he started.

At first sight this result is unexpected, but it was predicted long ago by Joule, who, in the appendix to a paper read at the British Association in 1843, states thus:—"If an animal were engaged in turning a piece of machinery, or in ascending a mountain, I apprehend that, in proportion to the muscular effort put forth for the purpose, a diminution of the heat evolved in the system by a given chemical action would be experienced."

This is evidently the key to the whole subject, and I hope shortly to publish other results, now in an incomplete form, which bear on the point.

It is evident that the potential energy which results from ascending a hil is gained by the expenditure of work, and a loss of heat from the body must naturally follow; while in walking on level ground, the potential energy acquired when the foot is lifted, and the consequent slight loss of heat, is neutralised by the *internal* work necessary to prevent the foot having any actual energy at the moment it touches the ground.

Upon this theory it is clear that the fall of temperature must be greater as the height arrived at is more considerable; and that the body must soon regain its normal temperature when the experimenter ceases to ascend. Lortet's observations agree perfectly with these requirements, he finding that his temperature was normal in less than half an hour after he had reached the summit.

In descending a hill the temperature ought evidently to rise greatly if this explanation is the true one.

Hailstones

I HAVE frequently observed that when hailstones are large and well formed, they are almost invariably round and smooth at one end, and roughly conical at the other (as in the annexed sketch), so as to suggest the idea that they are broken portions of spheres, of a structure radiating from the centre.

Perhaps some of your correspondents can inform me if there is any proposed theory which accounts for this peculiar form, which should throw some light on the formation of hail.

ENCOURAGEMENT TO NATURAL SCIENCE AT TRINITY COLLEGE, DUBLIN

NOTICES have from time to time appeared in this journal of scholarships, exhibitions, &c., obtainable in various colleges at Oxford and Cambridge, for proficiency in the purely Natural Sciences. From these we see that the neglect with which the study of nature has been treated is gradually giving way, and that our great Universities are at last becoming alive to the importance of this branch of learning, and to the necessity for encouraging its pursuit among the students. It is a matter for surprise that no similar mention of rewards for Natural Science is ever made with respect to the University of Dublin. And yet, were a Fellow of Trinity College asked what was being done in this direction at his University? he would probably answer, "Oh, a great deal! there are gold and silver medals awarded at the Moderatorship Examination for Natural and Experimental Science; then there are four or five Science Scholarships given annually." It is true a student may take out his degree with honours in Natural Science, and receives a medal, but let us see what is the course for the so-called Science Scholarships; the subjects are mathematics, pure and applied, for which 350 marks are obtainable, and, as a secondary course, either logic or physics, for which fifty marks alone are given. Such are the rewards and inducements held out to the student of *Natural* Science. It is scarcely to be wondered at that the most promising men in the University do not go in for them, but devote themselves to the more profitable classics or mathematics. For these the rewards are liberal and numerous; there are no less than seventy foundation scholarships, and many others, besides a great number of exhibitions, of which, within the last few months, thirty in addition have been granted by the Board. Not one of these has the man who devotes himself to chemistry, zoology, botany—in short, to Natural Science—a chance of obtaining. We ask—is this fair? Even supposing it unadvisable to divert any of these scholarships or exhibitions from their accustomed channels, yet surely the Board might establish one or two additional ones out of the—confessed to—60,000*l*. annual income.

About a year ago it was rumoured that a "studentship" would in future be given at the degree examination to the first gold medallist in Natural Science, but the idea seems to have died a natural death, and those in whose bosoms a ray of hope had arisen have been doomed to disappointment. It is not to be supposed that the authorities of Trinity College, Dublin, are in any great degree adverse to changes. On the contrary, when a reform (?) is not especially needed, they are not unlikely to introduce it; thus, for instance, the harmless old custom of setting the college clock a quarter of an hour late—giving the students, as it were, a quarter of an hour's law—has been abolished, and the hour for "commons" has been altered.

But we have no wish to lead any one to imagine that an altogether bigoted and unchanging spirit pervades the University: we have much pleasure in saying that many of its institutions are truly liberal; and we can scarcely doubt that before long the governing body will look with more favour on the Natural Sciences, and that they will become aware that Ireland—not so very flourishing at present—will be anything but a loser when the National University sends forth a greater number of scientific men.

A.

THE CONSTRUCTION OF HEAVY ARTILLERY

II.

CHOICE OF MATERIAL

IN an article which appeared on the 24th of last month, we endeavoured to explain the construction of our large ordnance, and to trace briefly the steps by which the combined strength and simplicity of the present pattern in the British service—the Woolwich Gun, as invented by Mr. Fraser—were attained. Simplicity is one chief element of strength; the fewer pieces anything is made of in general the stronger it is, and it has also the advantage of cheapness; but simplicity is seldom the beginning, it is rather the end of a series of inventions and improvements, and this has been the case in gun manufacture.

Having traced the steps of the process, and glanced at the history of its development, one topic more remains to be treated in order to give completeness to the subject, and that is the choice of material; and although the choice of material must come first in actual construction, to know the manner in which the gun is formed, and the qualities sought to be developed in the construction, will be a great help in understanding what qualities it is desirable that the material should possess. There are two qualities between which the choice lies; these are *hardness* and *toughness*. The British Government has decided, we think wisely, in favour of the latter. Hardness is the proper quality to resist a statical force, or pressure; toughness to resist a dynamical force or blow, and the explosion of gunpowder is not only a dynamical force, but it is the greatest that we have to deal with in any mechanical problems. If a hard substance is subjected only to a blow which it is quite able to resist, whose strain is well within the limits of its elasticity, then it is a very fit and proper material for the purpose; and this was the case with the old smooth-bore guns, which were all cast-iron. They were quite strong enough to do with safety all that was required of them. But for the force now imparted to rifled projectiles with their immense range, their tremendous armour-piercing *vis viva*, cast-iron guns are altogether inadequate. Much lower charges than those of our wrought-iron rifled guns would burst them into fragments. Did nature supply us with a material so hard that the strain of gunpowder was easily overcome by it, it would do very well for all guns. If, for instance, diamonds existed of sufficient size that a piece of heavy artillery might be bored from one, then they would be a very admirable material for the purpose. But, as this is not the case, we must fall back on tough instead of hard substances, the more especially as it does not do to approach the limit of resistance, for hard and crystalline substances have often flaws which no inspection can discover, and which only reveal themselves at the moment of destruction, and also such guns, when they burst, always do so explosively, without previous warning. This is not the case with tough material, which can yield through a very considerable extent before breaking. It may be objected that this could be overcome by increasing the thickness of cast-iron guns. But it is found that, after a limit very soon reached, increase of thickness does not produce increase of strength. The following law has been ascertained, that "no possible thickness can enable a cylinder to resist a pressure from within greater per square inch than the tensile strength of a square inch bar of the same material." That is—to take an example—if a cylinder of cast iron, whose breaking strain is ten tons per square inch be subjected to that amount of interior pressure, it will from the very first occasion begin to give way. At first, the inner surface would be ruptured, and the expanding gas or other source of pressure, taking advantage of the fissures, would quickly extend and complete the work of destruction. The inner portions of such a cylinder have much more work to do than those farther out, the same amount of force acting over a greater extent of surface or lamina. It may therefore be roughly estimated that the strains on the successive portions or rings vary inversely as the square of their radii. Dr. Hart, Fellow of Trinity College, Dublin, taking into account the compressibility of the metal, has given the following formula, $\frac{\sigma}{s} = \frac{r^2}{\rho^2} \frac{R^2 + \rho^2}{R^2 + r^2}$, where s is the strain on the inner surface, σ that on a ring of which ρ is radius, and R and r are external and internal radii of the cylinder. To compare the strains on the inside and outside, let S be the latter, and, as $\rho = R$, the formula becomes $\frac{S}{s} = \frac{2r^2}{R^2 + r^2}$. Applying this to the case of a gun of ten inches calibre, with a thickness of side of five inches, $r = 5$, $R = 10$, and S is to s as 50 to 125, so that more than twice as great a strain is borne by the inner surface as by the outer.

This brings us face to face with one of the great objections to cast-iron guns. In all castings the outer part, which cools first, is stronger than the interior. The metal contracts in cooling, and as the heat first leaves the exterior it first becomes solid, and the inner particles successively unite to it in layer after layer of crystals; so that the centre contains metal but imperfectly coherent. In a casting of two or three feet diameter, a central portion of six, eight, or even more inches in diameter, is found consisting of a spongy mass of scarcely coherent crystals of iron, sometimes with cavities visible to the eye when a section is made. This is exemplified in the annexed drawing (Fig. 1) of a 13-inch sea-mortar shown in section with the head of metal with which it is cast remaining attached, the parts to be cut off and bored out being marked by a black line. The shaded portions represent the weak and porous parts of the metal, which extend down through the centre below the bottom of the powder chamber, where it leaves a soft spot, easily hammered and burnt away by the shock and blaze of the discharge. It is plain that in any piece of artillery thus formed, the strength of the sides must gradually decrease from the exterior to the interior, which is precisely the reverse of what is required. To remedy this the Rodman cast-iron guns, used in the United States, are cast round a core or closed tube, which is inserted in the mould and represents the bore of the proposed gun. Into this tube a stream of cold water is kept continually pouring, so that the molten metal first solidifies round it; and, further, to secure this a fire is kept up round the mould for some time after the casting has begun. Here we have the conditions required in a cast-iron gun, viz. the best and strongest metal in the interior round the bore. Fig. 2 represents a 15-inch Rodman cast in this manner. It will be observed that in its shape, which resembles a soda-water bottle, all angles are avoided and a rounded form carefully preserved. By this another source of weakness is avoided, through compliance with an important law of nature. When any substance solidifies under the influence of heat leaving the mass, "the principal axes of the crystals will always be found arranged in lines perpendicular to the bounding planes of the mass, that is to say, in the lines of direction in which the wave of heat has passed outwards from the mass in the act of consolidation." (The Construction of Artillery, by R. Mallet, M.I.C.E., &c., &c. 1856.) This direction is that of least pressure within the mass, being that of the motion of the heat waves; and the law above stated is part of the far more general principle that in nature the line of least resistance is the one invariably chosen. From this law it follows that wherever there is an angle or sudden change in the form of a casting, through that angle there runs a plane of weakness, arising from irregular crystallization, as the crystals arrange themselves perpendicularly to the surfaces. Every abrupt change in the form of the exterior of a casting, every salient or re-entering angle, no matter how small, upon the exterior of a gun or mortar, is accompanied by one or more planes of weakness in the mass. This was strikingly exemplified in the cylinders of the hydraulic press made for raising the tubes of the Britannia Bridge. The first was made with a flat bottom, consequently it had planes of weakness as shown by the lines VV in Fig. 3, and under the enormous pressure to which it was subjected it gave way, the bottom curving out in the direction of those lines. The second cylinder was made with a rounded bottom, as in Fig. 4, and successfully resisted the pressure to which it was exposed. Cast-iron guns give evidence in bursting of planes of weakness in accordance with this law. The usual lines of fracture are shown in Fig. 5. Any visitor to Woolwich Arsenal can, by inspecting the cemetery where the guns burst in proof or for experimental purposes are preserved, verify this law of nature from many examples. By the form of the Rodman gun this source of weakness is avoided. It is a cast-iron gun, made on thoroughly scientific principles, in which the material is used to the utmost advantage, and therefore it may justly be compared with the Fraser gun, in which the same thing is done with wrought-iron, to measure the value of two materials. A casting is always cheap compared with a forging; in this point the Rodman has the advantage. But at its best, cast-iron has only one-third the strength of wrought-iron. Consequently the Rodman gun cannot be safely rifled. It fires heavy round shot, but with a range and accuracy greatly inferior to that of an elongated rifled projectile. Its initial velocity is high, but it is not long kept up. At close quarters its *racking effect* upon armour plate would be very severe, but its penetrative power is low. In the extensive experiments made at Shoeburyness in 1868 the 10-inch Fraser gun of 18 tons weight penetrated fifteen inches of iron (in three 5-inch armour plates), upon which the Rodman 15-inch gun of 20 tons only made a shallow indent. Further, being cast-iron, they are liable to burst explosively without any previous indication, and from the metal being in a state of great tension, being cooled from the inside, they have been known to break up in store.

The facts stated in the comparison of the best and most scientifically-constructed cast-iron with wrought, seem to be very decisive against the former. Two other materials have to be noticed. One is bronze, or gun-metal. It has some admirable qualities for making a gun. A bronze gun is hardly ever known to burst under ordinary circumstances. So great is its tenacity that with continued firing such a gun has been known to swell and change form without bursting.

But there are two objections to its use for heavy artillery that are decisive against it:—It is very expensive. The respective cost of guns of the several materials treated of in this paper may be taken in general as stated in the following table:—

Cast-iron guns . . .	£21	per ton weight of gun.
Armstrong wrought-iron	£100	„ „
„ „ Fraser construction	£65	„ „
Steel on Krupp's or Whitworth's plan .	£170	„ „
Gun-metal	£190	„ „

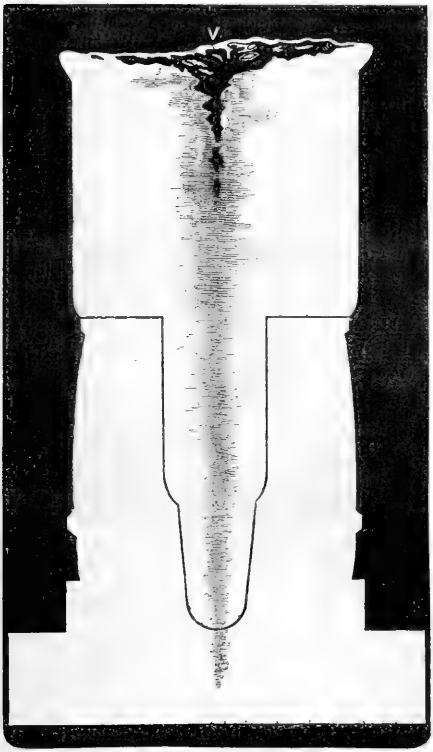

Fig. 1.

But a still more fatal objection to gun-metal for heavy pieces of artillery is its softness, and the rapidity with which it becomes heated. It is therefore quite unfit for the large charges of powder and immense rifled shot, with its severe friction on the bore, which are used in armour-piercing guns. Even small bronze guns, when fired repeatedly, exhibit the curious phenomenon of "drooping at the muzzle." This has been very interestingly explained by Mr. Mallet in the valuable work before referred to, and shown to arise chiefly from the rapidity with which that metal takes up heat. For large guns it is a material out of the question.

The last material to be spoken of is a far more formidable rival to wrought-iron, namely, steel. Of this Krupp's guns and Sir Joseph Whitworth's guns are constructed. The latter are made in a series of cylinders like the Armstrong coils, and which fit very tightly one over the other, and are forced on each other by hydraulic pressure. The former are bored out of huge solid ingots, which have been hammered to give them a fibrous character. Now steel has some admirable qualities as a material for heavy guns. It is very hard; and this makes it very suitable for the grooves of a rifled gun which have to bear such severe friction from the shot. For this reason all our wrought-iron guns are provided with an inner tube of steel. Moreover, it is very strong; the average breaking weight of a bar of steel of an inch sectional area is thirty-one tons, against twenty-five tons for a similar bar of wrought-iron (in the direction of its fibre) and ten tons for cast-iron; and when toughened by being tempered in oil the breaking weight rises as high as forty-five tons to the square inch. The reason why steel is so much stronger when tempered in oil instead of water, is, that the boiling point of oil is so high (600° F.) that it withdraws the heat very slowly from the red-hot mass plunged into it, compared with water, which is turned into vapour at 212° F. The steel for the tubes of the Woolwich guns is always thus tempered. But though steel has these admirable qualities as a material for heavy artillery, there are very grave objections to its use, and, on the whole, good reasons for preferring the wrought-iron guns to any steel ones that have yet been made. One is the greater cost, as shown in the table given above. A much stronger reason is, that though steel bears a gradual pressure so well, such as that of a testing machine for the breaking weight, it is brittle under a very severe dynamic strain or blow. When a steel gun bursts, it does so explosively without previous indications of yielding, and breaks up into fragments like a cast-iron gun. Another objection, and one perhaps even still more weighty, is that it is very difficult to make steel in large masses homogeneous throughout, and free from flaws. It is very much a chance whether it is so or not; and in the case of a gun, this is determined by the fact of its not bursting in service, but cannot be settled by a few proof shots beforehand. A good steel gun is a weapon of wonderful power and very great endurance. But one apparently exactly the same, and made in the very same way, in fact a twin gun, may burst before the hundredth round, or even at the first or second. From time to time, inventions of some process to make steel cheaply and of a homogeneous texture are announced. When some such announcement passes into realisation, it will be time for our Government to abandon a system which arms the country with guns at a moderate price, of a power which weight for weight is not surpassed by those made on any other system, and whose endurance may after proof be relied upon. Our gunners have no reason to be afraid of their own guns. Many of the continental Governments have been supplied with Krupp's steel guns, but very frequently they have burst in an unceremonious and unsatisfactory manner. On one occasion, the director of the Artillery Depôt at Tegel, near Berlin, was killed by the unexpected bursting of a steel 4-pounder gun. The manner of manufacture shows that steel is not calculated to bear a high dynamic strain. At the great gun factory at Essen the steel is hammered with steel hammers of immense weight, as much as 50 tons; but they are single action hammers, lifted up by steam, and allowed to fall by their own weight.* The 12-ton hammer used for forging our wrought-iron guns, which is

* The greatest achievement of Krupp's Gun Factory is a fifty-ton gun to fire a 100lb shot, which he presented to the King of Prussia; a fitting present to make a monarch. It cost nearly 10,000*l*., and occupied ten months of labour, night and day, in its manufacture. It was exhibited at Paris in 1867. Alas, that it should now return there under far different circumstances! But the manner of its construction cannot claim the merit of high scientific principles. A steel tube was formed sufficiently strong to resist the discharge; but as this would be so light that the recoil would hurl it into the air, like the toy cannons of our boyhood, it had shrunk round it enormous cast-iron rings or tubes. This was metal used for weight and not for strength. Whereas, the scientific principle very fairly laid down by the late Captain Blakely, R.A., is that "a gun should, if possible, be constructed in such a manner that each part of its mass would do its due proportion of work at the instant of firing."

driven down by steam power, has much greater dynamic force than the far heavier ones with which Krupp forges his steel. But the steel would break and crumble under a swift blow.

From what has been stated, it will be understood that the wrought iron now used for our guns, which was adopted upon Mr. Fraser's recommendation previous to his invention of our present system of construction, is of a soft and cheap character, instead of the hard, steely iron, which is much more expensive, and of which the guns were formerly made. The bars for coils are made in the Royal Gun Factories from scrap-iron, and from the stock of obsolete

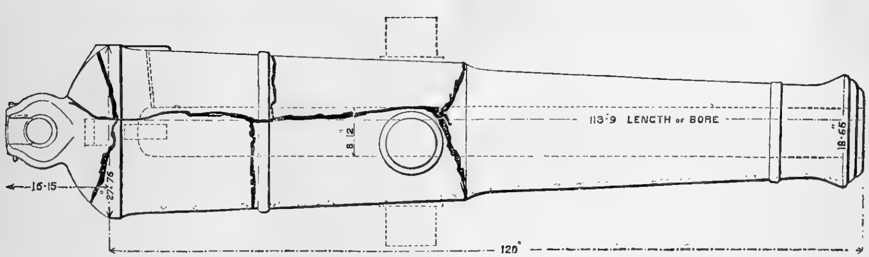

FIG. 5.

cast-iron ordnance. By this a very great economy is effected. Major Palliser has in another way utilised the old cast-iron guns by enlarging the bore and lining it with a wrought-iron and steel tube. The cost of this is about two-thirds of a Fraser gun of the same calibre; but they cannot be equal to a gun made entirely of wrought-iron.

In investigating the structure and materials for heavy guns, we see two great powers of nature wrestling before us: the strongest material and the greatest dynamic force, that of explosives, which man can use, and in the struggle some of her more recondite laws are exhibited in action. Each burst gun lying in the *cemetery* has its epitaph (if we could read it) written by the hand of nature, and telling accurately the cause of death. Those few that have been here deciphered and put together may form, it is hoped, a not uninteresting page in her note-book.

The authorities for most of the statements in this paper are, besides Mr. Mallet's very valuable work before referred to, two exceedingly interesting papers in the Proceedings of the Royal Artillery Institution, by Captain F. S. Stoney, R.A., Assist. Supt. Royal Gun Factories, entitled "A Brief Historical Sketch of our Rifled Ordnance," and "The Theory of Gun Architecture."

NOTES

WE learn by telegraph that the Sicilian section of the Eclipse Expedition, under Mr. Lockyer's directions, arrived safely at Rome on the morning of the 12th; thanks to the capital arrangements made by Mr. Vignoles with foreign railways for the transit of the party. Through carriages for the observers and instruments were taken from Ostend over the Brenner Pass to Verona; and they would have been sent further had not a breakage occurred in passing over the Brenner. The party intended leaving Naples for Syracuse in H.M.S. *Psyche* in the course of yesterday. All the Governments are aiding to the utmost in their power.

WE are glad to be able again to report favourably of the state of both Sir R. Murchison and Prof. B. Stewart. The former has continued to gain somewhat in strength, and the progress of the latter from day to day has been as satisfactory as could be desired.

WE have to announce that Mr. C. L. Bloxam has succeeded the late Dr. W. A. Miller as Professor of Chemistry in King's College, London, and that Dr. Debus, F.R.S., has been appointed Examiner in Chemistry to the University of London, in the place of the late Dr. Matthiessen.

PRESIDENT WOOLSEY of Yale College, U.S.A., has announced his intention of resigning his office. He has been President of Yale for more than a quarter of a century.

L'ABBE MOIGNO has discontinued the publication of his *Les Mondes* owing to the scarcity of paper and the impossibility of sending his periodical to the subscribers. L'Abbé Moigno, however, attends regularly the sittings of the Institute. M. de Parville is now the scientific editor of the *Journal Officiel*, as in former times. He is the only contributor to that paper who has been kept in office, which is highly creditable both to M. de Parville and to the French Government. M. de Parville's contributions are pirated by almost every French paper published in Paris, the only exception being the *Liberté* when M. de Fonvielle was in Paris. Now, *Liberté* must do like others. Reports on scientific matters are published in the *Journal Officiel* with more regularity and space devoted to them than in former times.

M. DECAISNE, Professor of Agriculture at the Museum, has laid before the French Institute, of which he is a member, a scheme for the early growing of cabbages, radishes, &c., &c., which are to be sown in land richly manured, kept for a fortnight, and used stem and root, as a new description of vegetable. This diet is intended to protect Parisians against scurvy when the use of salt beef becomes still more frequent than it is now. The working of this scheme is superintended by M. Toigneaux, the editor of several agricultural papers. Different pieces of waste land close to the walls were appropriated, and vegetables of that description must be now actually on sale.

AS soon as the investment of Paris was completed, the authorities took measures for preventing the destructive effects of shelling. Bills were printed and affixed to almost every house with directions for stopping the fire set up by the bursting of shells. Large tubs, filled with water, were placed on every floor of the large houses and private buildings. Although covered carefully with canvas, the water, having been left for weeks and weeks, became corrupted and fœtid. Proper instructions were given for stopping the infection by the using of charcoal. Two of these tubs are placed in the hall where the French Academy held its sittings, and two others in the *Salle des pas perdus*, by which visitors and members are introduced to it.

M. BARRAL, well known for the part he took in balloon experiments twenty years ago, has volunteered with his son for the balloon service. M. Barral was for many years the editor of the *Presse Scientifique*, a periodical which was discontinued a few years ago.

THE *Société Chimique* continues its sittings, devoted exclusively to warlike, culinary, and sanitary purposes. This body has offered a gun to the Provisional Government. It was built on new principles, and paid for out of the funds of the society, which do not flow out of the national exchequer, the *Société Chimique* being one of the very few French scientific bodies which are not supported by the State.

M. DUMAS is always in earnest for any improvement of diet. He has patronised the use of gelatine obtained from the carcasses of oxen, sheep, and pigs, by hydrochloric acid. The French Institute appears to have reversed the verdict given thirty years ago against the gelatine as proposed by D'Arcet, the only difference being that gelatine is not now prepared by steam, but by the action of acid on animal products, and that a new name, *osseine*, is given to the substance. He has also supported a scheme for grinding the whole of the corn, except the exterior coating, and the making of the flour so obtained into bread. But there is so large a quantity of corn and flour at Paris that the Government, although approving the scientific principles of this new method of grinding corn, declared the suggestion to be useless for the moment.

THE same answer was given to another suggestion, relating to the roasting of the corn for making a kind of gruel called *bouillie romaine*. It appears that this was the diet of the Roman legions, and that the gruel so obtained is very acceptable indeed. A kitchen for public distribution was said to be opened, but Government interfered, thinking, very properly, that it would be good to delay such steps for many weeks. They will use it only if the siege is prolonged so long that there is some danger of actual starvation.

M. BERTHELOT, although not a member of the French Institute, is the president of a standing committee for using scientific discoveries in the defence of Paris. That committee holds its sittings at the Ministry for Public Instruction, of which M. Jules Simon is the head. Many valuable suggestions have been adopted by that committee, which was closely connected with the Committee of Barricades, presided over by Rochefort.

M. JAMIN, the celebrated Professor of Natural Philosophy at the Sorbonne and member of the French Institute, has enlisted as a private in the artillery of the National Guard, and is doing his duty regularly, although begging for a weekly authorisation from the lieutenant in command to enable him to attend the sittings.

THE two Becquerels, father and son, have left Paris, and their place is filled by supernumeraries. Some papers have remarked very sharply upon it, and asked for the discharge of the younger.

THE following notification has been issued from the Home Department respecting the International Exhibition of 1871, dated Simla, October 11, 1870:—His Excellency the Viceroy and Governor-General in Council has been pleased to nominate the following gentlemen to form a Central Committee to assist the efforts of private individuals and others who may be willing to forward the objects of the Annual International Exhibition of Select Works of Fine and Industrial Art and Scientific Inventions, to be held at South Kensington on the 1st of May, 1871 : President, the Hon. Sir Richard Temple, C.S., K.C.S.I.; Members, his Highness the Maharajah of Jeypore, G.C.S.I., the Hon. B. H. Ellis, C.S.; Major-General the Hon H. W. Norman, C.B.; the Hon. J. Bullen Smith ; the Maharajah of Vizianagram, K.C.S.I.; Mr. W. G. Romaine, C.B.; Mr. E. C. Bayley, C.S., C.S.I.; Colonel the Hon. F. Thesiger, C.B.; Mr. Allan Hume, C.S., C.B.; Mr. H. Rivett-Carnac, C.S.; Lieut.-Colonel Baigrie, B.S.C.; Major O. T. Burne, Private Secretary to his Excellency the Viceroy. Honorary Secretary, Mr. H. Rivett-Carnac, C.S.

AT the meeting of the Royal Geographical Society, held on Nov. 29, a paper was read "On the Geography of the Sea Bed," by Capt. Sherard Osborn, R.N. The author gave an account of our present knowledge of the configuration of the bed of the ocean, as derived from Admiralty surveys and submarine telegraph expeditions during the last fifteen years. His explanations were illustrated by a number of diagrams showing sec ions of the North Atlantic and other oceans. It has been definitely ascertained that the greatest depth of the ocean does not reach 3,000 fathoms in any part where telegraphic lines have been laid. The bed of the North Atlantic consists of two valleys, the eastern extending from 10° to 30°, the Western from 30° to 50° West longitude. The extreme depth of the eastern valley is under 13,000 feet, which is less than the altitude of Monte Rosa. This valley has been traced southward to the equator. It is separated from the western valley by a ridge in 30° West long., in which the average depth is only 1,600 fathoms. This ridge terminates to the north in Iceland, and southward at the Azores, so that it is volcanic in its character at both extremities. Its extreme breadth appears to be under 500 miles, and the Atlantic deepens from it on both sides. Explorations carried on in the Mediterranean, the Red Sea, and the Indian Ocean, showed similar uniformity in the level of the sea-bottom ; and the general conclusions arrived at by Capt. Osborn were that in the deep sea there is an absence of bare rock, and that there are no rough ridges, canons, or abrupt chasms. Moreover, that the bed of the deep sea is not affected by currents or streams, even by those of such magnitude as the Gulf Stream ; but that it rather resembles the prairies or pampas of the American continent, and is everywhere covered with a sort of ooze or mud, the *débris* of the lower forms of organic life. In the course of the discussion, Professor Huxley said that, viewed on a great scale, there would be but slight difference between the large general features of the ocean bed and the dry land ; but that the smaller features would be different, as the effects of denudation would not appear in the deep ocean bed. To the naturalist, the observations of the telegraphists were of great importance, as showing the existence of low forms of animal life in the deepest seas ; and recent discoveries had shown that the most characteristic organisms of the deep-sea beds, named coccoliths and coccospheres, existed at all depths, even in shallow shore waters, and were also found fossil in sedimentary rocks of all epochs—a discovery of great interest, as confirming the view of the uniform conditions of submarine deposits in all ages of the earth's history. He was opposed to the view that the animals found living in the dark regions of the lowest sea depths depended for light upon the phosphorescence of some of the species, and saw no reason for concluding that they could not, like fungi, exist without light. He also doubted the accuracy of the very low temperatures said to have been found at great depths, and thought that those taken in the Indian Ocean might be explained by the fact that they were taken with thermometers not rectified for pressure.

AT a meeting of the Scientific Committee of the Horticultural Society, held on the 7th inst., a remarkable paper was read by Mr. Andrew Murray, on the subject of Mimetism, especially as exhibited in the instances of the South American butterflies, which have already been discussed in our columns. Mr. Murray adduced a number of arguments which he considered told against the theory that the Mimicry had been produced by Natural Selection, and attributed it to Hybridisation. We hope to be able to publish the paper in a future number.

A CONFERENCE of gentlemen interested in Scientific Education was held in the Royal Institution, Liverpool, on Tuesday night, the 6th inst., and unanimously passed a resolution declaring the advisability of establishing a Science College in that town, the cost of which was estimated at about 50,000*l.*, and a committee was appointed to take steps with the view of carrying out the object. Possibly the recent meeting of the British Association in Liverpool may have given an impetus to so laudable a design, which we hope may be successfully carried out.

A NEW quarterly journal is about to be published by Messrs. Groombridge and Sons, under the title of *The Landowner and Farmer's Note Book.* It will aim at presenting a well-arranged series of notes and suggestions in connection with estate and farm management.

MESSRS. LONGMAN intend to issue early in 1871 a Supplement to "Watts's Dictionary of Chemistry," bringing the record of chemical discovery down to the end of the year 1869. It will form a volume of about 900 pages, and many of the former contributors have consented to furnish additions to their articles.

THE new general Government of Elsass proclaimed by the King of Prussia, embraces, in addition to the departments of the Rhine which constituted the former Alsace, the arrondissements of Saarbourg, Château Salins, Saarguemines, Metz, and Thionville, taken from the departments of Moselle and Meurthe, in Lorraine. With the addition of these districts, the boundary of the new province marks out very nearly the German-speaking part of France. The fortresses of Thionville and Metz in the north, the natural barrier of the Vosges Mountains, and again the fortress of Belfort, in the south, will then protect the frontier of Germany towards France. From an article in the December number of *Petermann's Mittheilungen*, we learn that the new government has an area of 5,825 English square miles. This space is represented in English soil very nearly by the counties of Hants, Surrey, Sussex, and Kent, and it cuts off a thirty-sixth part from the whole of France. The fertility and industries of Elsass, however, support a population of 1,638,500, or a twenty-third part of the inhabitants of France, and the density of its population is comparable to that of the plains of China. In the new government the purely German-speaking area measures 4,425 square miles ; the purely French parts, which lie chiefly round the fortresses in the north and south, are together 985 square miles in extent, and the territory of a mixed language, which lies in patches between, makes up an area of 415 square miles.

THE series of botanical diagrams by Professor Balfour, of which we noticed the first some time since, is now issued in a complete form by Messrs. W. and A. K. Johnston, and comprises four large sheets 4ft. 2in. by 3ft. 6in. on rollers and varnished. They supply a marked desideratum for botanical teachers and lecturers, supplementing, but not replacing, Prof. Henslow's diagrams published by authority of the Science and Art Department. In the latter we have delineations of a plant belonging to each of the most important natural orders, with details of their structure. In Prof. Balfour's diagrams, each separate organ is taken, and the different variations of its form and structure illustrated. The first sheet showed the organs of plants generally, the tissues, root, and stem; in the second we have leaves and their modifications; in the third, inflorescence and the whorls of the flower, while the fourth presents us with the pistil, ovule, and seed, and the organs of flowerless plants. Many of the drawings are, strictly speaking, diagrams, that is, artificial representations of typical structure. They are well and clearly drawn, and sufficiently coloured to add to their lifelikeness. With these sheets, and either Henslow's series, or better still, a few hand-made ones on a larger scale, and actually taken from life, the botanical lecturer would be well provided; and the comparatively low price at which they are published ought to insure for them a very large sale. The handbooks which accompany them are admirably drawn up.

FROM China samples of Poyang Lake coal have been forwarded to the Admiralty authorities in the hope that they may be found useful for the navy in that station.

THE Government of India has taken further measures for carrying on coal borings in Central India, but only in Berar, and not in the Nizam's dominions.

THE Indian Government have again deputed Mr. T. W. H. Hughes, of the Geological Survey Department, to prosecute the investigation of the Wurda River coal-beds in the Central Provinces, and to report on the line of railway best calculated to develop the collieries.

OUR Darjeeling hill district of India is likely at length to experience a development of its mineral produce, instead of being left to depend on tea culture. Limestone, copper, and iron have been discovered not only in the Darjeeling territory, but also in the lately annexed Dooars of Bhootan. The Nepaulese have applied to work the iron ore, and the Commissioner of Kooch Behar has been authorised to divide the tract into sections, and to let out the mineral privileges by the year to the highest bidder.

A VERY important discovery of silver is reported from Copiapo, in Chile, which has a large silver district. El Carmen Mine is now producing 16,000 marcs of silver per month; that is 128,000 ounces, worth about 32,000*l.*

MR. JAMES GALBRAITH sends to the *Ararat and Pleasant Creek Advertiser* (Victoria), of Sept. 16th, an account of some huge boulders found near the townships of Hamilton and Coleraine, which he believes to have been deposited there by the agency of ice. He states that the whole of the western district of Victoria is covered with boulder clay. The ironstone gravel called buck-shot, which is found in patches on the surface and at a short distance below the surface, all over the plains to the south of Ararat and Beaufort, is, no doubt, a deposit from floating ice. The "grey stone" on the Ararat and Port Fairy road has been floated to its present position by ice; and a number of granite boulders on the road between Moyston and Ararat, some of them a great deal larger than the "grey stone," must have been brought to their present position by the same agency. No polished or striated rocks have, however, as yet been detected in the colony.

WE learn from the *New York Times* that an ice machine, constructed on Tellier's principle, is now being exhibited in the United States. The material used is gaseous ammonia, which is liquefied by pressure. It is said that the machine will make 100 tons a day, at a cost of four or five shillings per ton; and that the ice made by it is transparent and durable. The cooling effect of the vaporisation of liquefied ammonia may be applied to chambers containing articles of food to be preserved, or refrigerators might be constructed on any scale. The holds of ships could thus be converted into refrigerating chambers with the greatest ease, offering a ready means for the conveyance of meat from one port to another in a wholesome state.

BALLOON ASCENTS FOR MILITARY PURPOSES
II.

BEING detained in England by unavoidable circumstances for some time longer than I expected, I will try to give the British public an adequate view of the action of our French Institute in the matter of balloon navigation; and will confine my criticism to an exposition of M. Dupuy de Lome's own views, which were supported by the Government, so far as to give to this learned man a credit of nearly 2,000*l.* for the construction of his balloon. Perhaps the observations I have published in the *Liberté* and offered to some of his assistants in private conferences, have produced some alteration in the original scheme. It is a matter of which I cannot be made aware by any means, and I must suppose things to be as they were when I left Paris in my own balloon.

M. Dupuy de Lome's balloon was to be constructed out of silk, and I understood that people were engaged in looking after the stuff in different Parisian fancy shops. But it requires a great deal of search to find silk enough to construct a large balloon somewhat larger than Mr. Coxwell's "Research" and having a larger surface besides in consequence of its intended elongated form, the spherical form being, as is known, the one which offers the largest capacity for the smallest surface.

It may be well to remark that balloons are somewhat elongated in the present fashion of building them, the elongation being vertical instead of horizontal as required by M. Dupuy de Lome's scheme. But the elongation of the balloon is a thing of which we will speak more fully in another place.

M. Dupuy de Lome was not afraid to have his balloon shaped like an egg, or, rather, like a fish with two tails and no head, but he did not wish to try it with pure hydrogen gas. It is not because he thinks that hydrogen gas is too expensive or too difficult to prepare, it is only because he supposes that hydrogen gas would escape in spite of varnishing. I cannot agree with him in this respect, not only because my friend Giffard's balloons have proved perfectly hydrogen-tight, but principally because ordinary balloons filled with hydrogen have done good service. Amongst these balloons I may mention the one which conducted the unfortunate Worth to be lodged in a Cologne cell, not by any fault of its gas-holding power, but merely because aëronauts were foolish enough to open their valve when Prussians were firing at them, and preferred trusting to Prussian humanity to relying upon the dark mantle of the night.

Official people engaged in ballooning seem to have strong prejudices against hydrogen gas, as may be noticed from their acts; the battery I had caused to be constructed for filling poor "Liberté," having been wholly disregarded by them as unfit for use.

Many inventors have published descriptions of working aërostats, but very few of them were really professional aëronauts. I shall be justified by facts in stating that scarcely any of them was in a position to form an adequate idea of the most essential features of any really scientific scheme. Almost everyone of them has forgotten that the principal condition of success is an easy working. M. Dupuy de Lome has not avoided that fault, and his balloon is to be shaped, as we have remarked, like a fish, which is to be kept in an horizontal position. That condition is very difficult to accomplish when you have to look to so many other things at the same time. M. Dupuy de Lome is so well aware of the difficulty of having his balloon always progressing horizontally, that he proposes to get rid of it by keeping the balloon always filled either with gas, or with ordinary air by means of a pump. It is an instance of avoiding our old French saying, *Le remède est pire que le mal.* This saying is so much the more justified, that M. Dupuy de Lome is not contented with sending air into his balloon when it is required to fill it. He has constructed ready for the purpose a special balloon, which is to be enclosed within the large one, and which being alternately filled and unfilled according to the requirements of the external pressure, keeps the balloon always in a state of full expansion. The pressure inwards is always a little greater than the pressure outwards, which is in itself a new objection, as this artificial pressure increases the rate of escape for the gas by the small holes which are unavoidably so numerous in the whole surface. Besides, if there are some defective places, they may probably be opened by that pressure.

As you may understand from this explanation, M. Dupuy de Lome was very careful, and his scheme is worked out with every required detail, to show the corollaries which follow from the first assumptions. M. Dupuy de Lome being a very clever ship constructor, is ready to meet the difficulties, but he was not willing to avoid them at once by having a more simple scheme to work out. It is so much the more to be wondered at, if this clever aëronaut has not adopted this policy, inasmuch as he does not profess to go against the wind, but to design a contrivance which may help aëronauts in using the wind for a certain purpose, as returning to Paris from a town located at some distance, as Lille, Le Mans, &c. M. Dupuy de Lome intends to attain the desired result by making a definite angle with the direction of the reigning wind, which supposes on the part of the aëronaut some previous knowledge of the state of atmospheric currents, their change of duration, and different directions at different elevations; the principal feature of his intended directing balloon being the grand idea of having the motive power like an auxiliary implement for giving to the balloon differential motions. It does not, of course, prevent the aëronaut from using the deflections and variations of the wind according to the elevation of his balloon at any moment. The working out of these aërial manœuvres supposes necessarily that aërial navigators can know at any moment the place where they are. It requires constant attention from the aërial travellers, who are supposed to be supplied with every possible instrument for looking over the land and finding the places on the map prepared for that very purpose. It would be of itself a most interesting chapter, the better construction of such maps, as well as the determination of the means by which public authorities could give warnings to the aërial travellers. But in the present state of things, I should not be justified if I did not abstain from giving details which may prove useful to the invaders of my native land. I will be satisfied with saying, moreover, that the taking of the point in sailors' fashion is quite out of the question. The only condition is the view of the land remaining always at the command of the observer, or only being lost for short intervals, during which more than the usual attention is required. I have invented an apparatus called an *aërial planchette*, for helping aëronauts in the determination of their way, but from the experience of my last excursion I have lost every confidence in my instrument. I think that it is quite useless; the only thing required being good maps and better eyes, helped by powerful opera-glasses. The power of these can be enlarged by a very simple contrivance, which I mention merely to show that I know what is still to be done in this respect.

The question of the motive power to be employed is not of so much importance as was supposed at the first instance; and it is very easy to understand why, admitting that we want only a slow motion. I should not object, of course, to a quick displacement; but I am satisfied it cannot be obtained except by contrivances very difficult to imagine, and even more to realise, and besides it is not required for the special purpose in view, the returning to Paris from a French city which German armies have not occupied. The rate of motion will be improved by degrees, and will not amount to a large increase, except by the use of steam engines, which requires a great many preliminary steps to prevent the gas of the balloon from being lighted by the fire from the furnace, which would lead to the destruction of the balloon and of the aëronauts. The simplest contrivance will be the best if it proves useful. I should advise to arrange the motor apparatus so that it could be used by hand, and, besides, that it could be very easily thrown overboard like ballast in case of need. These two conditions being of much importance for our purpose, if I start for Paris, which I hope will be the case, I shall adhere strictly to them.

I have no objection to use a rudder, which may be constructed in a manner very easy to understand, but I should feel very much disposed to dispense with it. I think that a propelling machine may be arranged so that no rudder at all will be put into operation. I am afraid to give more substantial explanations, which could hardly be offered without giving a full knowledge of my intended construction, which is not my purpose.

The contributions of M. Dupuy de Lome to the *Comptes rendus*, have been sharply commented upon by the *Aeronaut*, a special paper devoted to the aërial navigation worked out by the *plus lourd que l'air* system, as inaugurated by Lalandelle and Nadar, and many other gentlemen of very little or no scientific qualifications. But every scientific man must confess that these interesting papers constitute by themselves a very valuable acquisition to general knowledge, independently of their special aim. M. Dupuy de Lome has given at the same time many calculations to show to what elevation a given balloon can attain under the conditions he has adopted, viz., constant fulness, and a certain excess of internal pressure for giving it a stability of form and of equilibrium.

Without quoting M. Dupuy de Lome's paper, and even correcting some parts of it, I will give a rough idea of the analytical questions involved in the calculation of the circumstances of an aërostatical ascent. I suppose, firstly, that the air has no horizontal movement at all, and that the only questions are to ascertain the elevation which the balloon may reach, the time that may be required, and the velocity with which the balloon ascends at the various points of its vertical course, as well upwards as downwards. There are besides two accessory suppositions which are required. The first is, that the balloon does not lose its gas by any *exosmose* during the experiment; and the second is that the temperature of the air, as well as the degree of moisture, is not altered in any degree. These conditions are hardly to be expected, but they are required for mathematically working out the analytical equations.

M. Dupuy de Lome, however, would not have been placed in a position to proceed with his calculations, if he had not very cleverly evaded the consideration of the other conditions, which are insuperable, owing to our imperfect knowledge of the atmosphere, as we shall see hereafter. W. DE FONVIELLE

PROF. WILLIAMSON'S INAUGURAL LECTURE TO THE FACULTY OF SCIENCE AT UNIVERSITY COLLEGE, LONDON

THE great value of scientific knowledge as a means of culture, a promoter of civilisation, and one of the most powerful levers of national prosperity, seems at least to receive its due acknowledgment in the land of Bacon and Newton, Sir Humphry Davy and Faraday. The recent efforts to introduce science into the public schools of England appear as a consequence of this recognition. A great variety of opinion, however, exists as regards the mode by which scientific knowledge ought to be imparted to the people. Some believe that a young farmer ought to be taught agricultural chemistry, the man at the furnace the chemistry of iron melting, and the maker of colours the chemistry of colours. This is what is called by many "technical education," for the promotion of which great efforts have been made of late. Technical education in this sense would be a mistake. It would not be difficult to show that it is impossible to teach, with any considerable effect, agricultural chemistry, which is the application of certain chemical principles to Agriculture, without a knowledge of these principles. These, with others, form part of the science of Chemistry, and it is clearly absurd to isolate them and teach their application in some particular case. The working classes of England want a knowledge of the elements of pure science; and they are sure to make useful application of this knowledge as soon as an opportunity offers itself. In this sense Professor Williamson expresses himself in his admirable lecture, "A Plea for Pure Science," * which on account of its sound views on some of the most important questions of the day, we recommend to the attention of our readers. On p. 3 Prof. Williamson says, "Now there are in education two great national parties, corresponding to the two most different points of view from which the preparation of any young person for his career in life can be considered. I submit that the progress of education will be proportional to the consistency and completeness with which the functions of these two parties are systematised and developed.

"The first step towards that object is to know and acknowledge their respective characteristics.

"One party looks to the special duties for which a young person has to be prepared and the material difficulties which he is expected to encounter. They see that the success and happiness of each individual are proportional to the efficiency with which he discharges the aggregate of the special duties of his station in life; and they accordingly recommend that each youth be placed in circumstances which may induce him to imitate accurately the doings of some one who is known to be successful in a station such as he is intended to occupy. The other party looks to the general qualifications which experience has shown to be most important for any success in life; and to the means by which they are most effectually acquired. They see that men who have been taught to understand and apply the best-known general principles are able to master a given set of practical details with a facility and completeness which other men do not attain. They know that a general principle of nature is an instrument of

* "A Plea for Pure Science." By A. W. Williamson, Ph.D., F.R.S.

thought applicable to the explanation of an infinite variety of phenomena, and they recommend that every one be placed in his youth somewhere where he may best learn such general principles. The first party takes little account of the development of the mental powers as a distinct object to be aimed at in education; the second attends but little to special operations.

"The former recommends special or technical instruction with a direct view to material success in a particular business, the direct aim of the latter is to educate and strengthen each individual mind. The essential differences between them arise from the fact that they look at the question from opposite sides, and respectively put forward what they see most clearly."

After this sketch of the outline of the characteristics of the two great parties, Professor Williamson describes some results of the arrangements recommended by them respectively. The great aim and object of science is to systematise our knowledge; and the discovery of an idea which helps to arrange any considerable number of facts in such a manner as to facilitate their apprehension, is the highest result of scientific work. We are then led in an admirable manner from the periodical disappearance of the sun to the law of gravitation as a model of scientific work. But it must not be supposed that the application of science to practical purposes is the greatest reward of scientific work. We read on page 12—

"To any one possessing a clear and vigorous mind, the acquisition of an idea which helps to explain things is a source of intense pleasure. He feels that it enlarges the scope of his mind, and gives him new power; and when facts, previously unintelligible, are explained by the aid of such an idea, they immediately acquire vivid interest and special value to his mind; such facts seem to gain life by acquiring an intelligible place in the system of nature.

"I believe that the triumphant feeling of the enlargement of his faculties which is experienced by a real student in the acquisition of any new law or principle of nature, is the most direct and vivid reward of his labours. The best and truest, as well as the most rapid progress in study, is made for the sake of that reward. Whoever has once enjoyed it will gladly seize any opportunities of wrestling, as far as his powers permit, with new difficulties, and mastering new ideas.

"It has been said that the happiness of an individual results from the due exercise of his various faculties, and this is surely not least true of the highest faculties of the mind; certainly those who have the power of understanding the wonders of nature derive great happiness from learning to employ it. It is like the pleasure which a man of healthy and vigorous frame experiences in climbing a mountain peak, and in enjoying, in proportion as he rises, a wider and more commanding view of things below."

Our space does not permit us to follow the author into the study of the conditions under which science flourishes, and does most effectively the good which it has to do, and we must content ourselves with a quotation of his description of the usual results which follow a system of special professional pupilage:

"But it often happens (page 15) that a man learns thoroughly the particulars of a business, as practised in some one successful case, and although he has sufficient capital and industrious habits, fails to realise similar results elsewhere.

"For instance, he has learnt and practised the management of a particular farm, and then takes a lease of one in another district. He purchases implements exactly similar to those which he has been using, and gets sheep and cattle of the same breeds. He adopts the same rotation of crops, and spares no pains to make everything go on precisely in the same way as that to which he has been accustomed.

"His first year is unprofitable; but he looks forward hopefully to better results, when things will have got into better working order. But the second and third year only bring more losses, and he is ultimately compelled to give up the farm.

"The next tenant is perhaps a man who has learnt the management of an adjoining farm, which happened to be in size, in soil, &c., very much like it. He uses ploughs and other implements which have been found to suit the soil, and gets breeds of sheep and cattle which thrive in that part of the country. He adopts the same rotation of crops and system of manuring which is customary in that district, and carefully imitates what he had seen to succeed, under conditions similar to his own. The result is that he goes on steadily year after year making a fair profit.

"Both of these men were mere servile imitators of what they had seen, and both had been taught to believe that a practical man ought to be nothing more, and that all theories are dangerous. Yet one failed while the other succeeded. We ought not to be surprised at the failure of the one, so much as at the success of the other, which was due to the exceptional circumstance of his finding a farm which admitted of being profitably managed upon exactly the same system."

Men of business, in the opinion of our author, ought to have not only a knowledge of things, but also of principles; and they must be able to use their knowledge of these things and principles for the purpose of bringing about special results; in fact they must have a knowledge of the laws of nature, and skill in the methods of applying that knowledge to experimental purposes. Their power of bringing about the material results from which they derive profit is proportional to the amount of such knowledge and skill which they possess.

And here we must break off our account of an essay which, no doubt, will greatly help to clear up our ideas about scientific and technical education.

ZOOLOGY

Researches on the Amœbæ

THE minute masses of protoplasm termed Amœbæ have been recently examined by M. V. Czerny, in relation to their resistance to reagents, and his results have been published in Schultze's "Archiv für Mikroscopische Anatomie," p. 158. He finds that the power of resistance to the action of solutions of common salt varies considerably in different individuals. In solutions containing one part to four hundred of water none died, but in those containing one to three hundred many died; whilst others, especially the quiescent ones, still lived in solutions containing one per cent., or more. None, however, survived when suddenly placed in a two per cent. solution. It is interesting to observe, however, that these lowly organised beings possess a certain adaptability to external conditions—a power of acclimatisation as it were, enabling them, if these conditions undergo slow alterations, to accommodate themselves to their new and modified surroundings. Thus, if the strength of the solution were gradually raised, it was found that some Amœbæ could continue to exist in solutions of four per cent. of salt. M. Czerny corroborates the statements already made by Kühne, that, on exposure to weak saline solutions, Amœbæ thrust forth numerous extremely delicate processes resembling cilia, and that they undergo fission. It is worthy of remark that the partially double contour of the *Amœba bilabiata*, which has led to the admission of a double contoured membrane in this species, is resolved, when examined with a No. 10 Hartnack immersion lens, into a number of closely aggregated, extremely minute toothlets, which, like the stinging cells, cover the whole surface of the body.

M. Engelmann has made some observations on the electrical excitation of the Amœba of the Arcella in the fifth volume of the "Nederlandische Archiv voor geneesen Natuur kunde," p. 28. His investigations were conducted in a moist gas chamber, with unpolarisable electrodes, the stimulus consisting of a single opening induction shock. In *Amœba diffluens*, as Kühne had showed previously, the results of the excitation differ according to whether the individual is in the active or in the quiescent condition. In the former condition, that is, when the animal is elongated or club-shaped and homogeneous, and its protoplasm seems to be flowing continuously in one direction, a very slight stimulus retards or altogether arrests the current, though it speedily recommences, the period of arrest not exceeding at most five seconds. If, however, the stimulus has been a little stronger, in addition to the arrest of the protoplasmic movements, a condensation and shortening of the whole animal occurs, and at a subsequent period perfectly transparent projections form in the anterior part of the body, into which the highly granular protoplasm streams until the original form of the Amœba, which sometimes moves forward with great rapidity, is re-established. The length of time occupied in these changes may amount with tolerably strong currents to about from one to two minutes. If the excitation be applied to the quiescent animal, the protoplasmic movements first cease, the mass assumes the spherical form, but instead of remaining quiescent, it now begins to move from place to place, in which active condition it may remain for a long time. From these experiments, and from others performed upon specimens of Arcella, containing air-vesicles M. Engelmann draws the conclusion that protoplasm, in consequence of electrical excitation, transitorily assumes the mechanical properties of a fluid.

CHEMISTRY

Constitution of Arbutin

HUGO SCHIFF has made some interesting experiments relating to the constitution of arbutin. This substance splits up into glucose and hydroquinone, just as salicin is resolvable into glucose and saligenin (Strecker). The relations between salicin and arbutin may be represented by the following formula:

$$\begin{array}{ll} C_6H_7 \left\{ \begin{array}{l} O \\ (OH)_4 \\ O \end{array}\right. & C_6H_7 \left\{ \begin{array}{l} O \\ (OH)_4 \\ O \end{array}\right. \\ C_6H_4 \left\{ \begin{array}{l} CH_2 . OH \end{array}\right. & C_6H_4 \left\{ \begin{array}{l} OH \end{array}\right. \end{array}$$

Salicin (Glycosalicyl alcohol). Arbutin (Glycohydroquinone).

The hydrogen in the oxhydryls of the glucosic portion of arbutin may in fact be replaced by acid radicals, just as the author formerly showed in the case of salicin (Zeitschr. (2), v. 1. 52). Moreover, the hydrogen belonging to the hydroquinone in arbutin is easily replaceable; whereas in salicin the hydrogen belonging to the saligenin is not capable of substitution.

Benzoyl-arbutins are obtained by means of benzoyl chloride; *acetyl-arbutins*, with acetyl chloride or acetyl oxide, which act at 60°–80°. The ultimate products of the reaction separated from the resulting solutions, after cooling, by means of ether, contain five acid radicals, and have this composition:

$$\begin{array}{ll} C_6H_7 \left\{ \begin{array}{l} O \\ (O . C_2H_3O)_4 \end{array}\right. & C_6H_7 \left\{ \begin{array}{l} O \\ (O . C_7H_5O)_4 \end{array}\right. \\ C_6H_4 \left\{ \begin{array}{l} O \\ O . C_2H_3O \end{array}\right. & C_6H_4 \left\{ \begin{array}{l} O \\ O . C_7H_5O \end{array}\right. \end{array}$$

Pentacetyl arbutin. Pentabenzoyl-arbutin.

They are colourless bodies, insoluble in water, slightly soluble in ether, more soluble in hot alcohol, from whence they crystallise on cooling in small shining needles. The acid radicals may easily be taken out again by boiling with weak bases. Together with the pentabenzoylated compound, the author likewise obtained *dibenzoyl-arbutin*, in which the hydrogen might be further replaced by acetyl.

Dinitro-arbutin dissolves easily in acetic oxide, and is converted into

$$\text{Pentacetyl-dinitro-arbutin} \quad \begin{array}{l} C_6H_7 \left\{ \begin{array}{l} O \\ (O . C_2H_3O)_4 \\ O \end{array}\right. \\ C_6H_2(NO_2)_2 \left\{ \begin{array}{l} O . C_2H_3O \end{array}\right. \end{array}$$

which may be separated from the acetic acid solution by water, and crystallised from hot alcohol in fine needles, insoluble in water, slightly soluble in ether. The alcoholic solution heated with sulphuric acid yields glucose, acetic ether, and dinitrohydroquinone, easily recognisable by the splendid colour which it gives with caustic alkalies. Dinitro-arbutin forms with basic lead acetate a crystalline orange-coloured lead-compound, in which the hydrogen of the oxhydryl is replaced by lead. Arbutin gives no precipitate, even with an ammoniacal solution of lead-acetate.

Recently precipitated silver-oxide is reduced, even at ordinary temperatures, by an aqueous solution of arbutin. On adding freshly prepared silver carbonate to a solution of arbutin heated to 50°–60° as long as carbonic acid is evolved, and heating for a short time with excess of the silver carbonate, a yellow solution is obtained, which no longer contains arbutin; but on separating the dissolved silver with a few drops of hydrochloric acid, and filtering, a solution is obtained, from which alcohol precipitates white flocks consisting of a compound formed by the union of 2 molecules of arbutin minus 2 atoms of hydrogen, viz.—

$$\begin{array}{l} \text{Diarbutin} \\ \text{or} \\ \text{Glycoquinhydrone} \end{array} \quad \left.\begin{array}{l} C_6H_7O \left\{ \begin{array}{l} (OH)_4 \\ O \end{array}\right. \\ C_6H_4 \left\{ \begin{array}{l} O \end{array}\right. \\ C_6H_4 \left\{ \begin{array}{l} O \\ O \end{array}\right. \\ C_6H_7O \left\{ \begin{array}{l} (OH)_4 \end{array}\right. \end{array}\right\} = C_{24}H_{30}O_{14}$$

This compound may be regarded as the glucoside of quinhydrone (green hydroquinone); it is related to arbutin in the same manner as helicoidin to salicin. Glycoquinhydrone is not at all bitter; it forms acetyl-derivatives when treated with acetic oxide, and an orange-coloured nitro-product with nitric acid. The latter, when decomposed in alcoholic solution by sulphuric acid, does not yield any substance that turns violet with potash. By means of zinc and sulphuric acid, hydrogen may be again added; and dinitro-hydroquinone thereby produced.

A solution of arbutin produces with ferric chloride a deep blue colour, which gradually disappears. None of the derivatives of arbutin above described exhibit this reaction.

Schiff also finds that *amygdalin* contains seven, and *phlorizin* five oxhydryl atoms, the hydrogen of which may be replaced by acetyl. Hence he assigns to these bodies the following formulæ:

$$\begin{array}{ll} C_6H_7 \left\{ \begin{array}{l} O \\ (OH)_4 \\ O \end{array}\right. & C_6H_7 \left\{ \begin{array}{l} O \\ (OH)_4 \\ O \end{array}\right. \\ C_6H_7 \left\{ \begin{array}{l} (OH)_3 \\ O \end{array}\right. & C_6H_3 \left\{ \begin{array}{l} OH \\ O \end{array}\right. \\ C_7H_6 \left\{ \begin{array}{l} O \\ CN \end{array}\right. & C_8H_8 \left\{ \begin{array}{l} CO . OH \end{array}\right. \end{array}$$

Amygdalin. Phlorizin.

(Zeitschr. f. Chem. (2) v. 519. Ann. Chem. et. Pharn. cliv. 237.)

SCIENTIFIC SERIALS

Poggendorff's Annalen, 1870, No. 7. The contents of this Number are:—(1.) "On the effect of Roughness of Surface on the Radiation of Heat," by G. Magnus. The author shows that the generally accepted explanation of the increased emission of radiant Heat by roughened surfaces, that it depends on a diminution of superficial density, is inadmissible. He attributes it to the refraction which takes place at the surface of emission, whereby the direction of the rays which leave the surface obliquely is changed. (2.) "On the Specific Gravity of Alcohol and of Mixtures of Alcohol and Water," by E. H. Baumhauer. A defence of the author's tables of the specific gravity of alcohol against Mendelejeff's criticisms contained in Poggendorff's *Annalen* for 1869, vol. 138. (3.) "On the Flow of Mercury through Capillary Tubes," by E. Warburg. The author's experiments prove that in glass tubes, whose diameter is a sufficiently small fraction of their length, the quantity of mercury which flows through them in a given time is directly proportional to the difference of pressure at the two ends, to the *fourth power* of the diameter, and inversely proportional to the length, but that it is independent of the absolute pressures at the ends so long as the difference remains constant. He concludes from these results that there is no friction, under the conditions of the experiments, between the mercury and the glass, but that the film of mercury in contact with the glass remains at rest while the inner portions flow through it. (4.) "Continuation of Investigations into the Electromotive Force between Liquids," by J. W. Müller. (5.) "On the Determination of the Proportion of Water in Glacial Acetic Acid," by F. Rüdorff. The author gives a table for deducing the proportion of water contained in acetic acid from the freezing point of the mixture. He gives 16·7° C. as the freezing point of pure acetic acid (without water), and finds that the presence of ½ per cent. of water lowers the freezing point by more than a degree. (6.) "On the Determination of the Freezing and Melting Points of Fats and other Compounds," by F. Rüdorff. The author points out the untrustworthiness of observations of melting points made, as they often are, by heating the substance to be examined in a capillary tube, or by coating the bulb of the thermometer with it. He recommends the observation of the freezing point, with a thermometer whose bulb is actually immersed in the substance, as a means of establishing its chemical identity instead of observing the melting point. To ascertain whether the observed temperature is the highest at which solidification can occur, he notices whether it is accompanied by rise of temperature, which always takes place if the body has been cooled below the normal freezing point. (7.) "On the Phosphorescence of Rarefied Gases after the passage of an Electric Discharge," by E. Sarasin. The author finds that the presence of oxygen, either free, or combined in a compound which is probably decomposed by the discharge, is an essential condition of the occurrence of the phosphorescence, and shows that this phenomenon is probably connected with the formation of ozone. Sulphuric acid vapour favours the production of phosphorescence in a high degree. (8.) "On the Electromotive Forces due to the contact of different metals," by E. Edlund. When an electric current traverses the point of junction of two different metals, a quantity of heat is absorbed or produced per unit of time which is proportional to the strength of the current and to the electromotive force acting between the metals. The author refers on this point to a previous paper (Poggendoff's *Annalen*, vol. cxxxvii.); in the present communication he endeavours to estimate the comparative electromotive forces acting between different pairs of metals by the heating or cooling effects of a current of measured strength. The junction formed of each pair to be examined was enclosed in the bulb of an air thermometer, and the difference between the expansions produced, when the current passed in opposite directions, was measured. The electromotive order of the metals deduced from the results did not agree with the order given by electroscopic observations (*elektrische Spannungsreihe*), but it agreed with the thermo-electric order, though the electromotive forces were not found to be proportional in all cases to the thermo-electromotive forces between the same pairs of metals. (9.) "On the Properties of Pictures formed by Photographic Lenses," by Dr. Hermann Vogel. The author calls attention to certain inherent defects of pictures formed by perfect photographic lenses, that is to say, defects not due to distortion or aberration in the lenses. (10.) "On the Velocity of Light in Quartz," by Victor von Lang, contains very careful measurements of the deviations produced by a quartz prism in the ordinary and extraordinary rays for various angles of incidence. Incidentally, a measurement of the ratio of the two coefficients of expansion of quartz is also given, deduced from the change produced by alterations of temperature in the refracting angle of the prism. (11.) "On the Specific Heat of Saline Solutions and Mixtures of Liquids," by A. Wüllner. The author disputes, on the authority of the experiments made in his laboratory by Dr. Schüller, Jamin's conclusion that when two liquids are mixed together, and therefore each of them is uniformly diffused through the whole of the space occupied by the mixture, the specific heat of each increases in proportion to increased space occupied by it. (12.) "On the Fusion of Leaden Bullets by striking against an Iron Plate," by Edward Hagenbach. This paper describes the melting of leaden bullets fired against an iron target, and contains a calculation showing that the kinetic energy due to the velocity assigned by "a competent military authority" is sufficient to account for the result. (13.) "An Experiment on boiling together two liquids which do not mix," by August Kundt. If steam is passed into liquid sulphide of carbon, or if sulphide of carbon vapour is passed into water, the resulting mixture of water and sulphide of carbon boils at 42·6° C., that is to say, at a temperature four degrees lower than the boiling point of sulphide of carbon alone. Also, if water and sulphide of carbon, which have been heated separately to between 43° and 46·6°, be mixed together, the mixture boils until its temperature has fallen to about 43°. These facts are in accordance with the observation of Magnus and Regnault that the vapour-tension of a mixture of two mutually insoluble liquids is equal to the sum of the vapour-tensions of the separate liquids. (14.) "On Microscopic Tridymite," by Ferdinand Zirkel. The author describes the characters of this mineral as seen under the microscope, and shows that it is of frequent occurrence in microscopic crystals. (15) "On Acoustical Attraction and Repulsion," by K. H. Schellbach, contains experimental proofs of the statement that "the sonorous vibrations of an elastic medium urge specifically heavier bodies towards the centre of disturbance, and specifically lighter bodies away from it."

Palæontographica. Beiträge zur Naturgeschichte der Vorwelt. Herausgegeben von Dr. W. Dunker and Dr. K. A. Zittel. Band xvii., Lief. 6, 1870. This new part of the well-known "Palæontographica" contains an interesting contribution to fossil entomology in the description of the species of diptera obtained from the brown coal of Rott in the Siebengebirge. It is from the pen of the distinguished entomologist, L. von Heyden. The species, which are figured, are forty-one in number, belonging to sixteen genera, and all but nine of them belong to the moisture-loving families of the monocerous group (*Tipulidæ*, *Culicidæ*, &c.). Of *Chironomus* there are five well-marked species, and no less than six different forms of larvæ and pupæ, and there is also the larva almost certainly of a species of *Stratiomys*.

The most important article in the *Journal of Botany* for December is a continuation of Dr. Braithwaite's Recent Additions to our Moss Flora, accompanied by two plates. Dr. Seemann continues his Revision of the Natural Order *Bignoniaceæ*, and Mr. Ernst gives Jottings from a Botanical Note-book, relating chiefly to Caracas plants. The other articles belong exclusively to specific British botany. With the new year it is intended to increase the amount of type in the journal by about one-third, without any corresponding increase in price.

SOCIETIES AND ACADEMIES

London

Zoological Society, December 6.—Robert Hudson, F.R.S., V.P., in the chair. The Secretary read a report on the additions to the Society's menagerie during the months of October and November, amongst which particular attention was called to an example of Geoffroy's Cat (*Felis Geoffroyi*), from Paraguay, purchased Oct. 10, and a specimen of the Antarctic Wolf (*Canis antarcticus*), from the Falkland Islands, presented by Mr. H. Byng, Acting Colonial Secretary of that colony.—An extract was read from a letter received from Dr. R. C. Cunningham, giving particulars of the habits of a Manatee, as observed by him in the public gardens at Rio.—A ninth letter was read from Mr. W. H. Hudson, on the Ornithology of Buenos Ayres.—Dr. J. Murie read the second part of his memoir on the anatomy of the Sea Lion (*Otaria jubata*), as observed in the male of this species which died in the Society's Gardens in 1867.—Mr. J. B. Perrin read a paper containing notes on the anatomy of the Smaller Fin-Whale *Balænoptera rostrata*), as observed on dissection of a young female specimen of this species captured at Weymouth in April, 1870.—A communication was read from Dr. G. Hartlaub and Dr. O. Finsch, containing the description of a remarkable new Finch from the Navigators' Islands, proposed to be called *Lobiospiza notabilis*.—A communication was read from the Rev. O. P. Cambridge, containing notes on a collection of *Arachnidea* made by Mr. J. Keast Lord in the Peninsula of Sinai and on the African borders of the Red Sea.—A paper was read by Mr. G. Gulliver, F.R.S., containing observations on certain points in the anatomy and economy of the Lampreys.—Dr. A. Günther read a notice of the hitherto unrecorded occurrence of *Lates calcarifer*, a fish belonging to the Perch family, in Australia.—A communication was read from Dr. J. E. Gray, containing the description of the skull of the adult *Eupleres gondoti*. This Madagascar mammal was previously only known from an immature specimen in the Paris Museum.—A second communication from Dr. Gray contained notes on *Hapalemur simus*, a new Lemur, described from a specimen lately living in the Society's Gardens.—Messrs. Sclater and Salvin communicated descriptions of five new species of birds from the United States of Columbia.—A second communication from the same authors contained an account of the collections of birds recently made by Mr. George M. Whitely on the line of the Inter-Oceanic Railway of Honduras.—Mr. Sclater read descriptions of three apparently new species of Tyrant Birds, of the genus *Elainea*, to which were added remarks on other known species of the same group.—Mr. St. George Mivart read a paper on the myology of a species of Chameleon (*Chameleon parsoni*).—Mr. Gould exhibited and pointed out the characters of two new species of Humming Birds recently collected by Mr. Buckley in Ecuador, which he proposed to call *Chætocercus bombilius* and *Thalurania hypochlora*.

Anthropological Society, December 6.—Dr. J. Beddoe, President, in the chair. Mr. W. R. Cooper exhibited and shortly described two Græco-Egyptian terra-cotta figures from the Hay Collection, showing a remarkable form of the head.—A paper was read by Mr. A. L. Lewis, "Suggestions and Reflections respecting the Peoples inhabiting the British Isles." The author divided the inhabitants of Britain into three leading types: 1st, the Kymric, long-headed, dark-haired, and light-eyed; 2nd, the Iberian, dark-haired and dark-eyed; 3rd, the Teutonic, broad-headed, light-haired, and light-eyed; the first two types being included under the collective name of Celt. After touching on some of the physical racial questions connected with the intermixture of these types, the paper concluded with some remarks tending to controvert certain popular ideas in reference to their mental characteristics, and their respective love of freedom, honesty, and chastity.

Entomological Society, Dec. 5.—Mr. A. R. Wallace, President, in the chair. Mr. Edward Saunders exhibited three new British *Hemiptera*, belonging to the genera *Salda*, *Plociomerus*, and *Hadrodema*. Mr. F. Smith exhibited *Baridius scolopaceus*, a beetle new to Britain, also *Calodera rubens*, both species captured in Kent. Mr. Butler exhibited a dark dwarf of *Vanessa urticæ*. Mr. Pascoe exhibited two new forms of *Longicornia* from the Himalayas. Mr. Albert Müller exhibited photographs of galls caused by several species of *Cynips*, sent by Mr. Bassett, of Waterburg, U.S.A. Mr. S. S. Saunders exhibited a living spider, *Eresus ctenizoides*, from Syra, where it lived under stones and fed on large grasshoppers; it had remained without food since July. The paper read was "A Monograph on the *Ephemeridæ*," by the Rev. A. E. Eaton. Mr. G. H. Verrall was elected a member of the Society.

London Institution, December 1.—Prof. Morris delivered a lecture "On Gems and Precious Stones," in which the characters of the various mineral substances used in jewellery were minutely explained. The diamond, the only representative among the gems of the elementary bodies, received special attention. The lecturer referred to its crystalline form, cleavage, hardness, specific gravity, and refractive power, the characters by which it is distinguished from crystallised quartz and other minerals. He described the dull and unattractive varieties of the diamond known as "carbonado" and "boort," and pointed out their application to steel-engraving, glass-cutting, and rock-boring. The mineralogical and geological features of the diamond-beds of India, Brazil, Borneo, South Australia, and South Africa, were discussed at length, and the frequent association of diamonds with itacolumite, gold, and rutile was referred to as a subject worthy of careful investigation. Other precious stones, such as the sapphire, ruby, emerald, beryl, topaz, jargon, garnet, spinel, and turquoise, were successively treated of, reference being made to their chemical composition, their physical properties, and their application to decorative and industrial purposes. To illustrate the lecture, Messrs. Blogg and Martin contributed a unique series of uncut diamonds exhibiting perfect crystalline forms, diamonds from South Africa, and one remarkable specimen embedded in the "cascalho," taken from a bed in Brazil. Prof. Tennant also contributed a splendid collection of diamonds in the natural state. Through the kindness of Messrs. Hunt and Roskell, the lecturer was enabled to show a fine series of precious stones and models of the great South African diamond before and after cutting. To Mr. James Gregory again, the lecturer was indebted for a collection of minerals used for ornamental purposes, models of celebrated diamonds, and samples of the gravels and rocks associated with the diamonds in South Africa.

December 5.—Dr. Odling gave his sixth lecture "On Chemical Action," and illustrated his remarks on the circumstances which modify chemical action by a series of brilliant experiments, in which the oxy-hydrogen blowpipe was largely used.

Chemical Society, December 1.—Prof. Williamson, F.R.S., President, in the chair. The following gentlemen were elected Fellows:—H. E. Armstrong, Ph. D., R. Barklie, W. L. Carpenter, T. M. Crafts, Prof. of Chemistry in Cornell University, J. Dewas, T. Farries, R. Mallet, F.R.S., and Dr. Ogg. Mr. Perkin, F.R.S., read a paper "On some derivatives of Anthracene." This was a detailed account of some Anthracene derivatives, more particularly of the products resulting from the action of sulphuric acid upon dibrom and dichloranthracene. Dichloranthracene is most conveniently prepared by passing chlorine gas over benzole, holding about one-fifth its weight of purified commercial anthracene in suspension, until the mixture becomes a crystalline mass. The product is then brought on to a linen filter, drained, washed with cold benzole, dried, and then further purified by distillation and subsequent recrystallisation from benzole. Thus obtained it appears in golden yellow needles. The mean of several analyses gave 67·91 per cent. C, 3·34 per cent. H, and 28·70 per cent. Cl, which numbers agree perfectly with the formula of Graebe and Liebermann, $C_{14}H_8Cl_2$. Dichloranthracene, when greatly heated, sublimes in beautiful needles, which may be obtained of considerable size. It is fluorescent in the solid state as well as when in solution. When a boiling solution of dichloranthracene in benzole is added to a similar solution of picric acid, the mixture assumes a dark orange-red colour, and on cooling becomes filled with small bright red needles. These consist of a compound of dichloranthracene and picric acid. A determination of the dichloranthracene in this body gave numbers closely approximating to those required by the formula, $C_{14}H_8Cl_2, C_6H_3(NO_2)_3O$. Dibromanthracene. This product was prepared by Graebe's process. It was, however, purified first by distillation and then by crystallisation from benzole. Thus obtained, it is of a golden yellow colour. It gave, on analysis, numbers closely agreeing with those required by the formula

$$C_{14}H_8Br_2$$

Like dichloranthracene, this body produces a beautiful red compound with picric acid. Action of Sulphuric Acid on Dichloranthracene. Dichloranthracene, when submitted to the action of fuming sulphuric acid, dissolves, forming a bright green solution, and is at the same time converted into a sulpho-acid. To prepare this acid, one part of dichloranthracene is added to about five parts of fuming sulphuric acid, and the mixture heated for a short time in the water bath. It is then gradually poured into several times its bulk of water and treated with carbonate of barium until all the sulphuric acid is neutralised. The acid solution, when filtered off from the sulphate of barium, is evaporated to a small bulk. When sufficiently concentrated, it becomes, on cooling, a shiny mass of minute orange-yellow coloured crystals, which may be drained on a porous tile. This acid has not been analysed, but, from the composition of its salts, evidently possesses the formula

$$C_{14}H_6Cl_2\begin{cases}HSO_3\\HSO_3\end{cases}$$

Mr. Perkin therefore proposes to call it disulphodichloranthracenic acid. It is easily soluble in water from which it is precipitated upon the addition of a little concentrated sulphuric or hydrochloric acid. It possesses a strongly acid taste and character. The acid forms salt with sodium, barium, calcium, and strontium. The barium salt is remarkable for its insolubility in hydrochloric acid.

Dibromanthracene yields with strong sulphuric acid an analogous disulphodibromanthracenic acid,

$$C_{14}H_6Br_2\begin{cases}HSO_3\\HSO_3\end{cases}$$

Its sodium, barium, &c., are similar to the salts of disulphodichloranthracenic acid.

Oxidation of disulphodichloro, and disulphodibromanthracenic acid. These sulpho-acids, when subjected to the influence of oxidising agents, rapidly decompose, exchanging their chlorine or bromine for oxygen, and are thus converted into disulphanthraquinonic acid.

$$\underbrace{C_{14}H_6Cl_2\begin{cases}HSO_3\\HSO_3\end{cases}}_{\text{Disulphodichloranthracenic acid.}}+O_2 = \underbrace{C_{14}H_6(O_2)''\begin{cases}HSO_3\\HSO_3\end{cases}}_{\text{Disulphanthraquinonic acid.}}+ Cl\,Cl$$

$$\underbrace{C_{14}H_6Br_2\begin{cases}HSO_3\\HSO_3\end{cases}+O_2}_{\text{Disulphodichloranthracenic acid.}} = \underbrace{C_{14}H_6(O_2)''\begin{cases}HSO_3\\HSO_3\end{cases}}_{\text{Disulphanthraquinonic acid.}}+ Br\,Br$$

An analogous result is also obtained by treating them with concentrated sulphuric acid, the following reactions taking place:—

$$C_{14}H_6Cl_2\begin{cases}HSO_3\\HSO_3\end{cases}+H_2SO_4=C_{14}H_6(O_2)''\begin{cases}HSO_3\\HSO_3\end{cases}+2\,HCl+SO_2$$

$$C_{14}H_6Br_2\begin{cases}HSO_3\\HSO_3\end{cases}+2\,H_2SO_4=C_{14}H_6(O_2)''\begin{cases}HSO_3\\HSO_3\end{cases}+Br_2+2\,SO_2+2\,H_2O$$

Anthracene when pure in large crystals shows a beautiful fluorescence, and so do many of the anthracene products, though curiously their solutions are comparatively poor in this respect. Anthracene and dichloranthracene in the state of vapour are not at all fluorescent, and moreover, a ray of light sent through the length of about four inches of the vapour of either body, still retains its power of rendering fluorescent bodies luminous. The experiments in this direction are, however, not yet concluded. On sealing up anthracene in a long vacuum tube with platinum poles, and allowing the discharge from an induction coil to pass through the tube, nothing particular is observed except the beautiful fluorescence of the crystals of anthracene. On examination with the spectroscope, the light showed carbon and nitrogen lines, the latter arising from the presence of a little air in the tube. Upon heating the tube, however, somewhat strongly, so as to volatilise the hydrocarbon, the ordinary colour of the discharge changed to a magnificent deep azure blue, and what is remarkable is that this blue light, when examined with the spectroscope, is perfectly continuous, and consists of blue with a little green. Dichloranthracene, when heated in a similar manner, gives an analogous result, but suffers a good deal of decomposition, anthracene changing but little. These curious results do not appear to be due to the fluorescent character of the substances employed, as napthaline produces a similar effect, the blue light, though not so intense, being continuous. It must be observed, however, that this hydrocarbon undergoes considerable change, becoming brown and oily. Anthracene heated in a vacuum tube in the same way gives a greenish blue light, showing faint carbon bands. On exposing a solution of disulphodichloranthracenic acid to the light of one of the recent displays of the aurora borealis it was very strongly illuminated, as might be expected. Moonlight, on the other hand, had no perceptible effect upon it, nor yet an alkaline solution of esculine. Mr. Perkin illustrated his interesting communication by a series of most beautiful experiments.

VIENNA

Imperial Academy of Sciences, October 20.—Dr. L. Manol communicated a memoir on chest and head voice, in which he described the condition of the glottis during the production of these two kinds of sounds.

November 3.—Prof. E. Stahlberger transmitted a memoir on the ebb and flow at Fiume.—Dr. Reuss presented a memoir on the Foraminifera of the Septaria clay of Pietzpuhl, containing the determination of the species figured by M. von Schlicht. Pietzpuhl possesses the richest Foraminiferous fauna of any known locality for the Septaria clay; the author has distinguished 164 species and twenty varieties, the total number found in the formation being 244 species.—Dr. C. Jelinek exhibited and explained a new anemometer, constructed for the station at Lesina, by Hipp, of Neuchatel.—Dr. T. R. von Oppolzer communicated a memoir on Winnecke's periodic comet, in which he endeavoured to show that this comet presents no extraordinary anomalies in its movement. This memoir also contained an account of the author's method of calculating disturbances.

November 10.—Prof. J. Gottlieb transmitted a chemical analysis of the Königsbrunnen at Kostreinitz, in Lower Styria, and a memoir by M. A. F. Reibenschuh, containing the analysis of the Johannesquelle, near Stainz, in Merau.—Prof. Loschmidt communicated a continuation of the results obtained by M. A. Wretschko in his researches on the diffusion of gaseous mixtures.

I. R. Geological Institute, Oct. 30.—Baron v. Richthofen, in a letter dated Pekin, July 20, gives a notice of his recent geological explorations in China. On the first of January he started from Canton and travelled through the provinces of Kwangtung and Hunan to Hankan, and then, through Hupe, Honan, and Shansi, to Peking. The most important result of this journey is the discovery of the enormous extension of coal-fields and iron-ores in the province of Shansi. The southern half of this province, about 1,500 German square miles, and probably also the northern half, is an almost continuous coalfield, containing anthracite of the best quality, in layers of from twelve to thirty feet in thickness. The anthracite district is much more extensive than that of Pennsylvania, and offers incomparably more favourable conditions for working. Together with the coal, iron ores of very good quality are found in abundance. —M. Th. Fuchs gives a sketch of different discoveries in the tertiary basin of Vienna which he made last summer, in company with M. F. Karrer. The building of the new aqueduct for Vienna has caused denudations near Baden, which prove clearly that the marine clay (Tegel) of Baden overlies the Leytha limestone. Between the Cerithium (Sarmatic) beds and the overlying Congeria beds, they discovered in many localities a thin stratum, which contains the fauna of both these formations mixed, without any sensible difference in the form or size of the various species. M. E. Tietze has explored the Jurassic and Liassic strata in the southern Banat, in the environs of Bersgasyka. He found that large masses of white and red limestones, which belong to the tithonic age, immediately cover the famous Ammonite bed, near Swinitga, which has long been known as belonging to the middle Jurassic formation. Farther down are developed different members of the lias, which contain considerable layers of coal.—M. G. Stache, during the summer, was occupied with the exploration of the central crystalline masses in eastern Tyrol, chiefly in the environs of the Ziller Valley. He brings full evidence that metamorphic stratified rocks, partly even with traces of organic remains, play a considerable part in the composition of the large mountain masses of that country.

GÖTTINGEN

Royal Academy of Sciences, October 19.—M. W. Krause read a paper on the termination of the nerves in the tongue of man; and M. P. Gordan a memoir on the partial differential equations, of which the resultant R satisfies a form of the n^t degree and a form of the m^t degree.

November 12.—M. R. Lipschitz communicated contributions to the theory of the reversal of a function system.—A paper was also read by Dr. R. von Willemoes-Suhm on a *Balanoglossus* from the North Sea. This paper contained the description of a third species of the genus discovered by the author in the Oeresund near Helleback, in Iceland. He names the worm *B. kupfferi*, and dredged it up from a depth of 12 to 16 fathoms in a bottom of fine mud.

November 16.—A paper on asymptotic lines, by M. A. Enneper, was read.

NATURAL HISTORY SOCIETIES

II.

IT must not be supposed that we expect, from Societies which have been but recently established, works of the importance or the completeness of those which we have mentioned * as emanating from the naturalists of Northumberland and Durham; or even such volumes as those annually issued by the Woolhope Club. It must be borne in mind that it is by no means necessary, or even advisable, that a young society should do much, or even anything, in the way of publication. The experiment of a local magazine has been tried in connection with more than one body, but in each case the results can scarcely be considered satisfactory. The Liverpool naturalists issued monthly such a publication—at first in lithograph, afterwards in print—which contained papers on subjects of general as well as of local interest. The High Wycombe Natural History Society started a similar magazine, on a similar plan, but issued quarterly instead of monthly; this continued for four years, but is now among the "things that are not." The Folkestone naturalists tried a like publication and with a like result; one year was sufficient to bring it to a close.

The failure of these periodicals is scarcely a thing to be regretted. The only scientific value of such local publications, it cannot be too often repeated, lies in the prominence given to local Natural History. It is not to be supposed that people even now, much less in the future, would refer to them for information—say on the Darwinian theory, or any other matter of general importance and interest—which would be found in fuller detail in magazines of wider circulation. Nor are popular descriptions of plants or insects of any greater value; and a physiological discovery of any importance should be communicated to some one of the many journals now open to naturalists. If such a discovery is recorded in a local publication, the chances are that it will be overlooked by the majority—simply because it is not in its proper place. The plea that Natural Science may be rendered more popular by such periodicals is worth but little; there are other magazines which, while wisely excluding local lists, are at once readable and scientific, and to them people really anxious to learn will turn for information.

The Folkestone Natural History Society has made a step in the right direction by publishing this year "A List of Macro-Lepidoptera occurring in the neighbourhood of Folkestone." This list occupies twenty-four pages, and is sold in a wrapper for 6*d*. As far as we know, this is the first of its kind; other bodies have issued local lists with their annual reports, but we have none published separately at a low price, like this of the Folkestone Society. The example is one which we hope will be followed; the funds of even a small field-club would be adequate to cover the expenses of printing, and the actual value to science of such a list is far greater than that of any number of local magazines containing papers of "general interest." The same society has in hand a list of the flowering plants of the district on the same plan, which will probably appear next year. The Belfast Naturalists' Club has this year issued with its report the first of a series of local lists; this has already been noticed in NATURE.

The system of dividing the labour of list-making, which is now coming into general use, may be regarded as a modification of the mode of working by sections, which we noticed in a previous paper. One or more members engage to superintend the making-out of some one list of the mammals, birds, lepidoptera, coleoptera, mollusca, fossils, phanerogams, or cryptogams. Each of these branches is, of course, capable of subdivision; and, where there are many workers, such subdivision is advisable. The Westmoreland naturalists have deputed one of their number to collect and examine the Batrachian Ranunculi of the district; and the investigation of certain "critical" genera and species might well occupy a careful observer for a considerable period. But we would lay especial stress upon the necessity of posting up regularly every scrap of information; books should be kept for the purpose, in which every discovery should be entered. By this means, and by this means only, can the actual state of the knowledge of any branch be ascertained; and it is easy to arrange for publication when required notes thus conveniently brought together. Whether for publication or not, however, and no matter how few and incomplete the records may be, it is the first duty of every Society, great or small, to register all its observations, not only for present benefit, but for the use of those who come after.

Although we would not urge upon every Society the "rushing into print," which is nowadays too common, we think we have reasonable grounds of complaint against one or two bodies, which have been established for some years, and number many members, in that they have not published more regarding the results of their labours. We may instance as an example the Manchester Field Naturalists' Society; and, as a notice of one or two of the more popular clubs falls within the scope of this paper, we may take this as a favourable specimen of them. Established ten years ago, chiefly through the energy of Mr. Leo H. Grindon, assisted by a few other Manchester naturalists, this Society soon counted its members by hundreds. At one time about five hundred and fifty names were enrolled, and, at the present date, between two and three hundred appear on its list. The work of the Society consists in the investigation, by means of excursions during the summer session, of the Natural History of the neighbourhood. These excursions are largely attended, and after the ramble the members assemble at tea, when addresses on scientific subjects are given. During the winter occasional *soirées* are held, which are rather too much like evening parties, with a little dilettante science thrown in; the room being decorated, extensive "toilettes" abundant, and instrumental music performed during the evening. The scientific "halfpennyworth of bread" to this "intolerable deal of sack" is provided by an exhibition of objects on a large scale, and the delivery of a paper or two, or a lecture, at some time during the proceedings. Of course, neither excursions nor *soirées* can be got up on this large scale without a proportionate outlay; and the result of this is that, although the annual subscription is 10*s*. 6*d*. —much too high, by the way, for such a body—the

* See NATURE, Vol. ii. p. 469.

balance in hand, when all expenses are paid, is inconsiderable. We do not wish to be misunderstood when we express our opinion, founded upon personal observation, that a large proportion of those who attend the summer excursions look upon them as merely pleasant afternoon rambles, and that of those who patronise the *soirées*, many go as they would to any other entertainment, without the slightest interest in Natural Science. There are good workers at Manchester—men, who from early youth have been strongly imbued with a love of nature, and who have done, and are doing, good service to science; and to their influence must be attributed the good effects which such a body certainly produces in spite of drawbacks. But, under the circumstances, it appears to us that instead of the somewhat lengthy, though interesting report, which is issued annually, containing detailed notices of the localities visited and papers read, which will be of little value to posterity, lists of the natural productions of the district, similar in plan to that published by the Folkestone Society, should be issued. One such list—that of the Mosses, by Mr. G. E. Hunt—appeared in 1864; and if only on the ground of showing that some real work is done, and of allowing the workers "fair play," a portion of the funds should certainly be devoted to the placing on permanent record, for the benefit of future observers, complete lists of the flora and fauna of the district. More especially at Manchester is such a record needed, inasmuch as the Committee advocate the establishment, "in places where they are likely to become permanently established," of plants foreign to the district, and of freshwater mollusca. This suggestion appears to us, under any circumstances, unadvisable; and unless some record is kept of such introductions, it must, if carried out, prove both misleading and injurious.

Those who contemplate the establishment of a field-club on a small scale will do well to content themselves with moderate beginnings. The subscription should be low—say 2*s.* 6*d.*; patronage should not be sought, but rather discouraged; and every pains should be taken to show that no class distinctions would be considered of the slightest importance in matters connected with Natural History. In one society, with which we were intimately connected, we well remember the difficulty we had to convince an intelligent working man, with a genuine love for science, that he was a welcome addition to our ranks; and it is only by judicious management that such can be induced to co-operate with those who are considered their superiors.

The High Wycombe Natural History Society, another of those which has aimed at popularising science, holds monthly evening meetings during the winter at the houses of some of the principal members. These meetings partake somewhat of the nature of a *conversazione;* tea and coffee are handed round, papers are read, objects displayed, and the evening concludes with an exhibition of the microscope. Despite all care, however, the intention of these gatherings has been somewhat lost sight of, and they have grown to be looked upon as mild forms of dissipation. To remedy this, the plan is to be adopted of holding fortnightly, between the general meetings, instruction classes, which only those who are willing to work are expected to attend. Each of these will last from an hour to an hour and a half, and be devoted to some one special point; and the benefit resulting from this arrangement seems likely to be considerable.

A great point to be remembered by those who are engaged in organising a local Society is that it is by no means to be desired that a large number of members should be enrolled; in fact, when once the body is established, and its existence generally known, we would solicit no one to join it. Those who really care for the thing, and are therefore likely to be useful members, will come forward readily enough to lend a helping hand; but those whose assistance has to be sought will probably be of but little use, even if it be obtained.

The subject of local museums in connection with Natural History Societies is now exciting some attention; and we have intelligence of the recent establishment of one at Folkestone upon what seems to be a satisfactory basis.

*THE PHYSIOLOGICAL LABORATORY AT LEIPZIG**

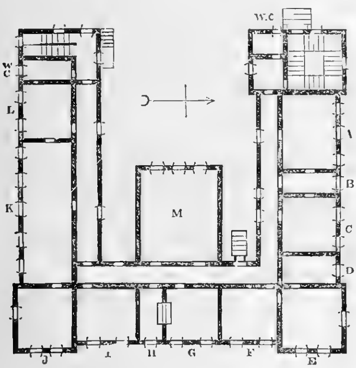
SINCE in England we have absolutely no physiological laboratory open to students, an account of the best in Germany (there are many others) will be interesting to the public. Perhaps some day the University of Oxford may think it desirable to erect such a laboratory to match that recently provided for Experimental Physics. There is plenty of money which the colleges could use for this object, if once they were freed from the old restrictions by the aid of the Government.

"The physiological laboratory, where I am at present working, owes its existence to the energy of Prof. Carl Ludwig, and to the liberality of the Government of Saxony. As it is universally acknowledged to be the most complete establishment of the kind in Europe, it seems to me to merit a somewhat detailed description. The building, as may be seen by the annexed plan, has somewhat the form of a horseshoe, with a small projecting portion in the middle, where the lecture-room is situated. The dimensions are—on the north and south sides, 119ft. 2in.: on the east side, 121ft. 11in. The right wing of the building constitutes the microscopical department, the left the chemical department of the laboratory, while the central portion is devoted to the study of experimental physiology in the narrower sense of the word.

"To describe the rooms more minutely. Room A is arranged for the accommodation of beginners in the study of microscopy, and is furnished with boxes that contain the microscopes, and a large ground-glass tablet, by means of which the lectures on microscopy are illustrated with drawings in coloured chalk. Room B is the private study of the assistant in microscopy. Room C is intended for more advanced students in microscopy, and contains an injecting apparatus, by means of which three different fluids can be injected simultaneously under any required pressure and for any length of time, while the injection mass and the tissue to be injected are heated over a water bath. Room D contains a small library, consisting of such books as are most needed for constant reference. Room E is furnished with glass cases, in which physiological apparatus is kept when not in use. As a rule, no experiments

* From the *Boston Medical and Surgical Journal.* Letter from Dr. H. P. Bowditch.

are performed in this room. Rooms F, G, and H are devoted to experimental physiology, and are furnished with operating tables, with bellows attached for keeping up artificial respiration on curarised animals, registering apparatus of various sorts for recording the pressure of the blood, water baths where any required temperature may be kept up indefinitely, an injecting apparatus like that in the microscopical department, evaporating closets, glass cases for apparatus, &c. Between Rooms G and H is a small closet arranged for observations with the spectroscope. Room I is the chamber where all experiments are performed which require the use of large quantities of quicksilver. It contains two quicksilver pumps for extracting gases from fluids, instruments for measuring the activity of the respiration in man and the lower animals, &c. Room J is divided into two portions, one of which is used



for a weighing room, and the other for experiments in acoustics. Rooms K and L contain, besides the ordinary furniture of chemical laboratories, the ingenious air-pump of Bunsen, by which the process of filtering is so greatly accelerated. The lecture room, M, accommodates about one hundred students. Tables running on a small railroad in front of the seats, enable the lecturer to demonstrate his experiments very conveniently. The room is lighted from above as well as from the side, and if necessary, can be darkened completely for optical experiments. In the basement of the building is a small gas-engine of about one-horse power, which drives the respiration apparatus, registering instruments, &c. In the basement are also the rooms where the animals are kept (one room being devoted entirely to frogs), a chamber furnished with refrigerators for performing chemical experiments, where a low temperature is required, a chamber containing furnaces for fusion, a workshop, store-rooms, &c.

"The second story of the building contains the rooms of Prof. Ludwig and his family, and those of other persons connected with the laboratory. In the court-yard is a small building containing the necessary arrangements for experimenting on horses and other large animals. Here, also, are an aviary and a small fish-pond.

"Besides the permanent and stationary apparatus already described, the laboratory is well supplied with all sorts of instruments for physiological experiments, and new apparatus is constantly ordered for special investigations. There is also a very skilful mechanic living in the laboratory, whose duty it is to make alterations or repairs in the apparatus as circumstances may require.

"Prof. Ludwig directs personally all the work done in the laboratory, devoting his whole time to the superintendence of his pupils, and making no independent investigations. Each of the pupils, at present nine in number, makes, under the direction of the Professor, a series of experiments with a view of settling some special point in physiology. The results arrived at are published at the end of the year, sometimes under the names of the Professor and pupil together, and sometimes under that of the pupil alone. The whole work of the laboratory forms every year a pamphlet of 150 to 250 pages.

"Prof. Ludwig lectures five times a week on physiology, and his assistants, viz., Prof. Schweigger-Seidel in microscopy, Dr. Hüfner in chemistry, and Dr. J. J. Müller in physics, also lecture on their specialties, besides superintending the work done in their respective departments.

"It will thus be seen that abundant facilities are here offered, not only for learning the existing state of physiological science, but also for becoming familiar with the manner in which physiology is at present studied in Germany. The patient, methodical, and faithful way in which the phenomena of life are investigated by the German physiologists not only inspires great confidence in their results, but encourages one in the hope that the day is not far distant when Physiology will take its proper place as the only true foundation of Medical Science.

"H. P. BOWDITCH."

Dr. Bowditch adds to this in a private note that *all* expenses, even down to the frogs used for experiments, are borne by the Saxon Government; so that the institution is absolutely free of charge to the student. Professor Ludwig welcomes to the laboratory any student—provided there is room for him—whether German, English, French, or Russian, who is desirous and capable of original investigation.

PALÆONTOLOGY OF MAN

Précis de Paléontologie Humaine. Par le Docteur E. J. Hamy. 8vo. (Paris, 1870. London: Williams and Norgate.)

M. HAMY'S Palæontology of Man, written with the view of bringing the results of recent discovery to bear on the antiquity of our species, is a most important contribution to the rapidly increasing literature of prehistoric archæology. It is intended to serve as an appendix to Sir C. Lyell's great work on the subject, and treats only of palæolithic man to the exclusion of the three newer prehistoric ages. M. Hamy has classified his materials with judgment and caution, and has collected into a small compass most of the statements on record of the existence of man in the geological past, with a running criticism, which sometimes admits, and at other times rejects, the testimony. He stands almost alone among his countrymen in attaching no importance to the reputed discovery of the famous Moulin Quignon jaw, and in allowing that the circumstances under which it was found were, to say the least, very equivocal. His book, in a word, is so good that I propose to draw attention to a few of the weak rather than the strong points. Among the latter, the first chapter, which treats of the employment of stone implements in the religious ceremonies of the ancients, and gives the history of "thunderbolts," is perhaps that which especially demands the notice of the English reader.

The evidence adduced by M. Bourgeois of the discovery of flint flakes and scrapers in the Miocene strata of Thenay, along with remains of the hornless rhinoceros and mastodon, proves, according to M. Hamy, that man was an inhabitant of Miocene Europe. It is, however, rejected by most of the French and English *savants*, because M. Bourgeois has not shown that the implements in question may not have been derived ultimately from the surface of the ground, where they are very abundant. While M. Hamy acknowledges this to be the case, he does not see its full bearing on the value of the testimony. The implements probably are of Quaternary, or even of post-quaternary age, and certainly cannot be considered decisive of the sojourn of man in Europe during the Miocene epoch, although the climate at the time was almost tropical, and the conditions of life easy. Nor can the evidence of the grooved bones of Halithere, found by M. Delaunay at Puancé in Maine-et-Loire be accepted, because it cannot be proved that the grooves may not have been caused by some other agency than that of man. The proof of the existence of man in Europe during the Pliocene epoch derived from the striæ in the fossil bones found at Saint Prest and in the valley of the Arno, accepted by M. Hamy, is equally unsatisfactory. The flint "arrow-head" (fig. 25) and other rude fragments said to have been obtained at the former place from the same horizon as the bones of *Elephas meridionalis*, by M. Bourgeois, the stout champion of Miocene man, do not afford the precise and exact testimony which is demanded for the establishment of the case. The presence, indeed, of man in Europe in the Miocene and Pliocene epoch is as yet non-proven, and we must be content to await future discoveries. The results of the labours of archæologists and geologists throughout Europe during the last ten years has not placed the advent of man further back than the river gravels of the Somme, and the epoch of the caves, both of which are post-glacial or post-pliocene, or quaternary, in other words posterior to the great submergence and refrigeration of northern Europe, through which many of the Pliocene mammalia were destroyed.

M. Hamy has done good service to the students of the Quaternary epoch by refusing to allow the validity of M. Lartet's divisions into the age of extinct animals, as distinguished from that "of those which have migrated." The intimate association of the remains of the two groups in the caves and in the river-deposits, renders such a division untenable. He also modifies the divisions of the Quaternary invented by M. Lartet—(1) the age of the cave-bear, (2) that of the mammoth and woolly rhinoceros, (3) that of the reindeer, and (4) that of the aurochs, by running the first and the last two into two groups, connected together by a series of transitions. In other words, in the application of M. Lartet's system, he finds it necessary to admit that the "ages" are more or less connected together, and have no very great value in classification. M. Lartet was undoubtedly correct in the view that the post-glacial or Quaternary mammals did not arrive in Europe *en masse*, but he has not shown us the order of their appearance, which is the very corner-stone of his system. So far as the geological evidence goes, the aurochs was probably living in the Val d'Arno in the Pliocene age, and the reindeer is found as abundantly in France, Germany, and Britain with the cave-bear as with the mammoth and woolly rhinoceros. Since, indeed, the Quaternary epoch succeeded the great lowering of temperature, it might, *a priori*, be inferred that the reindeer was one of the first animals to invade the then almost arctic regions of Central and Northern Europe. The caves, however, and the river-deposits, reveal nothing on this point; they merely prove beyond a doubt that all the Quaternary mammals were living here at the same time. It is very hard to understand why M. Lartet should have expected to find all the species of animals in one locality, and should have based his classification on the absence of some, and the presence of others, since in every living fauna the animals are unequally distributed. Nor is there any intelligible cause why some few animals should be picked out of a large fauna to the prejudice of the rest, for classificatory purposes. The Essay on the Post-glacial Mammals of Great Britain (Quart. Geol. Journ. 1869) demonstrated that the system will not apply to the British Fossil Mammalia, and M. Hamy's book implies that it is equally inapplicable to those of France, for which it was intended. It is not too much to say that our present knowledge forbids any attempt to subdivide the Quaternary epoch by an appeal to the animals living at the time. Archæologists may perhaps be able to classify the different forms of implements, but naturalists are as yet unable to learn the order in which Quaternary mammalia invaded Europe. The reindeer is quite as likely to have preceded as to have succeeded the mammoth.

W. BOYD DAWKINS

COOKE'S CHEMICAL PHILOSOPHY

First Principles of Chemical Philosophy. By Josiah P. Cooke, Jun., Erving Professor of Chemistry and Mineralogy in Harvard College. Pp. 533. (Macmillan and Co., London and Cambridge, 1870.)

THIS book is intended to be used by students who have attended lectures on experimental chemistry, or after a course of laboratory instruction; hence it deals merely with the theoretical principles of the science and their application for the solution of many practical problems of chemical research.

Every chapter and section is followed by a series of problems and questions which the student is recommended carefully to work out, and anyone who has mastered all the problems set forth will have attained a very considerable proficiency in chemical science.

In the introductory chapter we have definitions referring to volume and weight, and the author has adopted here, as in several other instances, different kinds of type in order to represent different relations. Thus, Sp. Gr. in italics means specific gravity referred to water as unity; the same symbol in ordinary Roman letters signifies that hydrogen is taken as the standard; and when printed in Old English type that air = 1. The distinctions between chemical and physical forces are here pointed out.

This chapter is concluded by twenty-three problems and questions referring to weights and measures and specific gravities. Throughout the book temperatures are expressed in centigrade degrees, and the metrical system is employed. Next, we have chapters on fundamental chemical relations and molecules, and the relations of the latter to heat. Chapter IV. treats of Atoms, and Chap. V. of Chemical Notation. Under this head we observe several definitions and modes of formulation which are not usual in this country. Thus chemical reactions are divided into three classes, analytical, synthetical, and metathetical, the latter including double decomposition, displacement, and re-arrangement. The symbols are usually printed in italics, but solid bodies are formulated in "full-faced" type, and gases in skeleton type; and when reactions take place in aqueous solution this is expressed in the equation by including the dissolved bodies in brackets with the symbol *Aq*: thus, $(Ca\ Cl_2 + H_2O + Aq)$ shows that the calcic chloride is in solution, and that the quantity of water represented by H_2O is a result of reaction. In the chapter on Stochiometry (though Stoichiometry seems more correct) are a number of modes of calculation of formulæ, and of the relations between weight and volume; and under Chemical Equivalency is a kind of constitutional formulæ which somewhat differs from those in general use. Professor Cooke follows the principle laid down by Dr. Frankland that chemical formulæ should represent, as far as possible, the relations existing between the atoms of a compound; but he has thought it advisable to place the grouping element or radical at the end of the formula instead of the beginning; this, we think, is to be regretted, as it adds another to our already numerous modes of formulation. Short strokes are placed at the side of the grouping element or radical to indicate the direction of the attractions; thus the formula for Ethylacetamide is $H, C_2\ H_5, C_2\ H_3\ O \equiv N$, showing that the hydrogen, ethyl, acetyl, are united directly to the nitrogen, the commas indicating that they are not united among themselves: Diethylurea $H_2, (C_2\ H_5)_2, \equiv N_2 = C\ O$ is another instance. When these short strokes become numerous they are rather confusing, as in Turquoise, $O_3 \equiv [Al_2]_2 \equiv' O_6 \equiv (P\ O_2)$. Graphic formulæ of Kekulé's and Crum Brown's form are explained, and students are advised to make frequent use of them, but not to abuse them. The nomenclature employed is that which is frequently used in England, and which Mr. Cooke designates as that of the London Chemical Society, though we think that some of the Fellows disapprove of such terms as zincic sulphate, &c. The physical relation of chemical bodies, as crystallography, electrolysis, spectrum analysis, and heat of chemical combination, are treated at some length. The elements are divided into sections according to their atomicity, the perissads being taken first and afterwards the artiads. This arrangement places oxygen beyond the middle of the book, instead of near the commencement as usual. The occurrence, mode of preparation, and properties, of the elements, and of their more important compounds, are very concisely given. Carbon is described as occurring in three forms, diamond, graphite, and *coal*. This last term seems an unfortunate one for amorphous carbon, as some coal contains as little as 73 per cent. of the element. Under the compounds of carbon is a section on Organic Chemistry which extends over only sixty pages Although it contains a vast amount of information, and organic compounds are mentioned throughout the book, yet it seems rather a meagre account of the enormous developments of this branch of science. At the end of the book are tables of French measures and weights, of elements, of the specific gravities of gases and vapours, and of logarithms and antilogarithms. We wish this book success, as it indicates great vitality in Transatlantic chemistry.

OUR BOOK SHELF

Elementary Treatise on Natural Philosophy. By Professor A. Privat Deschanel, of Paris. Translated and edited, with extensive additions, by Prof. Everett, D.C.L., of Belfast. In 4 parts. Part 1—Mechanics, Hydrostatics, and Pneumatics. (London: Blackie and Sons.)

THIS translation of Prof. Deschanel's "Traité de Physique" will, we believe, be found extremely useful. An elementary treatise of moderate size on Physics has been long wanted in our schools. Atkinson's translation of Ganot, or Brook's Natural Philosophy, is too expensive for general use, and of smaller books, none, so far as we know, are good. The issue of Dr. Everett's translation in parts at the moderate price of 4*s*. 6*d*., will enable it to be largely employed. The engravings with which the work is illustrated are especially good, a point in which most of our English scientific works are lamentably deficient. The present part contains Mechanics, Hydrostatics, and Pneumatics. The clearness of Deschanel's explanations is admirably preserved in the translation, while the value of the treatise is considerably enhanced by some important additions. Thus, to Deschanel's description of the pendulum is added a short account of the condition of isochronous vibration, moment of inertia, momentum, and kinetic and potential energy. In the section on Pneumatics, Deschanel's extremely good description of the air-pumps of Hawksbee, Bianchi, Kravogl, Geissler, and Deleuil, is supplemented by an account of Sprengel's mercurial pump. It is possible to point out defects, but they are few. The conception of "mass" is always a difficult one for a beginner. Deschanel gives a very clear explanation, which is not reproduced, the term being employed without explanation. Nor do we understand why, instead of Deschanel's statement that the co-efficient of absorption of ammonia in water at 0°C. is 1050 (exactly it is 1150), it is said to be only 600. But these are minor defects, and we repeat that we believe the book will be found to supply a real need. W. M. W.

The Wild Garden; or, Our Groves and Shrubberies made beautiful by the Naturalisation of Hardy Exotic Plants. By W. Robinson. (London: Murray.)

THIS little volume forms a fitting sequel to Mr. Robinson's admirable book, "Alpine Flowers for English Gardens," which we noticed some time back.* It does not contain nearly such a large amount of novel information, but will nevertheless be of great value to all lovers of their gardens. The book is a protest against the practice which commenced some twenty years since, and reached its height a year or two back, of throwing the whole energies of the gardener into producing large masses of colour by the use of what are termed "bedding plants," to the exclusion of the cultivation of the individual flower. This somewhat barbaric taste has resulted in the gradual disappearance from our gardens of many flowers which had been "household words" since the time of Shakespeare, to the great detriment, as Mr. Robinson considers, of gardening as a real art, and to the enormous increase of its expense.

* NATURE, vol. i. p. 603.

Our great traveller and naturalist, Mr. Wallace, says, that "during twelve years spent amidst the grandest tropical vegetation, he has seen nothing comparable to the effect produced on our landscapes by gorse, broom, heather, wild hyacinths, hawthorn, and buttercups." Mr. Robinson's aim is to make our gardens as beautiful as our hedgerows and woods; and to this end he would not have his favourite plants placed together indiscriminately in a bed; but, as far as possible, he would imitate the natural *habitat* of each species, and for this he gives full instructions in each case. Half the volume is occupied by a list of hardy exotic plants suitable for naturalisation in our woods, semi-wild places, shrubberies, &c., with directions for their cultivation; and we hope it may assist in again bringing the public taste to the culture of flowers beautiful not only in themselves, but from the historic associations connected with many of them. A. W. B.

Die Kleinschmetterlinge der Umgegend Münchens und eines Theiles der bayerischen Alpen. Von August Hartmann. 8vo, pp. 96. (Munich, 1871: E. Lotzbeck.)

THIS is a catalogue of the Micro-Lepidoptera of the neighbourhood of Munich, and of a portion of the Bavarian Alps, with indications of the plants on which the larvæ of the different species have been found feeding and of the times and places at which the species have occurred. In his Introduction the author describes the method which he adopts for killing and preparing the delicate little moths which form the subject of his book, and from this the collector of Micro-Lepidoptera may gain some important hints. He also notices especially the curious moths belonging to the group of Psychidæ, and those Tineidæ which resemble them in habits; and he fully confirms the statements of Von Siebold as to the occurrence of parthenogenesis in *Solenobia triquetrella* and *lichenella*. W. S. D.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Eozoön Canadense

IT is now about five years since a series of communications to the Geological Society of London by Logan, Dawson, Carpenter, and Sterry Hunt, announced the discovery of organic remains in the Laurentian rocks of Canada. They were decidedly interesting, not only as attempting to show that the belts of limestone interpolated in the great beds of Laurentian Gneiss were organic in their origin, but also from the *art* which the authors displayed in the mode of placing their views before the public. The realistic manner in which the fossil *Eozoön canadense* is drawn as it were from the *life*, coupled with the fixed belief in most men's minds that limestone is necessarily organic in its origin, predisposed many to accept the theory without much inquiry. The reputation of Dr. Carpenter as a physiologist was alone considered sufficient to settle the matter. These views did not, however, long remain unchallenged, for in the following year Professors King and Rowney, in a communication "On the so-called Eozoönal Rock," detailed the elaborate investigations by which they arrived at the conclusion that the presumed fossil was purely a mineral production. The replies that naturally followed were literally little more than reiterations of previous statements, excepting in the important admission from Dr. Carpenter, that the several features (that is chamber casts, canal system, and proper walls) could be separately paralleled elsewhere. He, however, took his stand upon the combination of the whole found in the Canadian specimens. To the fatal objection that all had been obtained from metamorphosed rocks Dr. Dawson replied by producing a specimen from Tudor, Ontario, which Sir W. E. Logan goes no further than to declare is from *comparatively* unaltered limestone, but which Dr. Dawson considers furnishes a conclusive answer to all arguments drawn from metamorphism. Since then I am not aware that any further evidence in favour of the organic hypothesis has been made public. On the other hand, Professors King and Rowney announced in a paper, read before the British Association at the Liverpool meeting, that they had discovered the features of the so-called organism in the Ophite of Strath in the Isle of Skye, an altered sedimentary deposit of the Liassic age, in which evidence of its mineral origin was conclusively proved. Here, at present, the matter rests; but in my opinion ample materials exist for forming a judgment, not by reliance on authority but by independent reasoning. With this object in view, and with your permission, I will proceed to detail a few of the facts of the case. Before doing so I would, however, call attention to the strange absence of any allusion to obvious objections which characterises the first series of papers, and to the persistent begging of the question involved in constantly speaking of the specimens as undoubted fossils. The adoption of this objectionable practice under authority of such eminent names is prejudicial to an impartial judgment, as it indirectly influences the mind. I am quite willing to admit that there existed sufficient reasons for suspecting them to be fossils, but I submit that it is not philosophical to state so distinctly before a thorough examination of all the objections. For evidence of this having been done I search these papers in vain. How then can any one, accustomed to scientific methods of investigation, help suspecting that under all this scientific and pictorial use of the imagination there exists or lurks a fallacy?

First, then, the specimen from Tudor has to be disposed of; nor will this be difficult, for it is altogether a lame affair. It is admittedly not from an unaltered rock, so it is difficult to see even how it bears on the question. The distinctive features are also obscure, and the chambers not of the usual form and proportion. To call this *Eozoön canadense*, and then bring it forward as closing the discussion, is an amusing piece of controversial skill. When it is more certainly co-ordinated with the original specimens, it will be time to discuss it. I simply ask, would it have been pronounced organic had it been the only variety discovered? I think not.

The broad fact then remains unshaken that in unaltered rocks no Eozoönal structures have yet been discovered. On the other hand, in metamorphosed rocks such structures are abundant, and even Dr. Gümbel, of the Bavarian Survey, a believer in Eozoön, has been much mystified by finding its features in impossible places. Not only do we find it in the Laurentians, but in rocks of a much later date, but curiously only in those that have undergone alteration. If it be an organism, then hydrothermal action, it seems, is necessary to its development, not as one would suspect during life, but ages after its entombment in sedimentary deposits.

The prevailing infilling material of the "chamber casts" representing "the sarcode body of the animal," is also admittedly serpentine or some analagous mineral—a mineral that forms the basis of no known fossil, consequently we are to assume that at each period of the animal's existence, either the conditions were different to those under which others were fossilised, or that the original infilling has since been replaced by serpentine; and this, be it said, must always have happened in those rocks afterwards selected for metamorphism.

Again, as minerals of this description are never found in unaltered rocks, we must be prepared to believe in the curious coincidence of the same rocks, and only these, having, at periods widely separated in point of time, been selected for the preservation of the organism and the deposit of these minerals. Either we must do this, or be prepared to show that metamorphism must necessarily change the infilling of the "chamber casts" to serpentine. Which supposition is the wildest?

Still further, we must believe that not only has Nature so miraculously preserved her pet animal, but that she has also imitated the fossil organism in the same minerals in an altered rock, in a manner to justify such acute observers as Professors King and Rowney in considering the imitation identical with the thing itself. For in the altered portion of the rock at Strath, before referred to, we have the features of the Eozoön, while the unaltered portion, which it gradually shades off into, teems with characteristic Liassic fossils. Have these fossils been obliterated in the altered portion, or have we the Eozoön again conterminous with the metamorphism?

And, in conclusion, we must further admit that all these conditions have been fulfilled over wide areas and at periods remotely separated with unerring regularity whenever the Eozoön has made its appearance. Is not this an improbability amounting to the impossible? For my part, this negative evidence far outweighs the "determination of its foraminiferal affinities by a point no larger than a pin's head," and I feel assured that whenever impartial geologists take the question up the fossil itself will become extinct. T. MELLARD READE

Blundellsands, Liverpool, Dec. 12

The Difficulties of Natural Selection

MR. WALLACE'S frank acknowledgment, for which I thank him, that he had in his two previous letters misunderstood my line of argument in what I consider one of the most important points at issue between us, absolves me from the task of again defending myself from charges of error and self-contradiction. As, moreover, Mr. Wallace has not accepted my challenge "to explain the nature of the intelligence which was operative in the creation of man, and which is a principle unknown in the rest of the organic world," it is impossible to pursue further this branch of the question. All naturalists will look forward with the most intense interest to Mr. Darwin's long-promised work on Natural Selection as applied to Man. There are, however, one or two subsidiary points raised in the discussion, to which I shall be glad of the opportunity of briefly referring. Mr. Stebbing, objecting to my attempted parallelism between mimicry and instinct, says that "it can hardly be said to be proved" that the extraordinary resemblances occasionally found in the vegetable kingdom are not protective or mimetic. I certainly think it can be. When we find an almost absolute identity between the foliage of a plant belonging to Africa and another growing in South America,* we are certainly justified in saying that one has not imitated the other, and that it gains no protection from the resemblance. Mr. Carvalho again makes merry over what he calls "my" argument, that imperfect imitation is, to all appearances, not beneficial in the cases published by Mr. Weir. The argument is not mine. I simply recount the observations made by practical entomologists, undertaken at the suggestion of Mr. Wallace himself. Mr. Carvalho's argument, which follows, is an instance of how, when a theory is once adopted, every conceivable fact may, by its too zealous advocates, be twisted to support it. Had these twig-like caterpillars been rejected by birds, it would have been considered a triumphant proof of the theory of Natural Selection; the fact that "they are eaten with great relish," we are told is equally "really in its favour"!

Westminster Hospital, Dec. 17 ALFRED W. BENNETT

* See NATURE, Vol. ii. p. 70.

Is Mimicry Advantageous?

THE discussion of mimicry among butterflies, in the recent numbers of this Journal, has brought to my mind some considerations which seem to have been overlooked by those who have treated the subject.

Of the fact of mimicry there can be no possible doubt, and in some instances it is even more striking than has been asserted. For instance, in North America, Messrs. Walsh and Riley have pointed out the resemblance between *Danais Archippus* and *Limenitis Misippus*; they might also have shown that in the extreme southern states where *L. Misippus* occurs, and *D. Archippus* is replaced by *D. Berenice*, the colour of the mimetic Limenitis deepens nearly or quite to the tint of the southern Danais.

But of how much actual benefit to the mimetic species is this so-called "protective" resemblance? It seems to occur where it can be of the least possible advantage to the species. The great sources of destruction here, as in all groups of animals, are in early life. How large a proportion of the eggs that are laid by butterflies ever finally produce imagines? Let those answer who have attempted to follow their history in their native haunts. My experience leads me to believe that, at the very least, nine-tenths—perhaps ninety-nine hundredths—never reach maturity. Hymenopterous and dipterous parasites beset them at every step; the eggs, although so small and often heavily ridged, cannot escape the ovipositors of the tiny Pteromali; while in attempting to breed caterpillars taken in the field, the chance is so greatly against the evolution of a butterfly, that hymenopterists actually choose this method of supplying *their* cabinets. "Of two hundred larvæ of *Pieris Brassicæ*," Mr. Drewsen, of Denmark, writes to me, "I obtained only twenty pupæ; all the rest were attacked by *Microgaster glomeratus*," and my own attempts with the larvæ of *Pyrameis Atalanta*, both in America and Europe, have been even more unavailing. These caterpillars seem to be peripatetic banquetting halls of Microgasters and Tachinæ.

Now it is a curious fact that while the globular egg of *Limenitis Misippus*, with its deeply-pitted shell, defended by long filamentous spines, is constantly attacked by parasites; and the grotesque, hump-backed, strangely-coloured caterpillar of the same species is likewise infested to an extraordinary degree, I have been unable to discover by very careful search any evidence that the egg or larva of *Danais Archippus* is ever pierced by a parasite; yet the egg is not small and only lightly ribbed, and the caterpillar large, fleshy, smooth-skinned, and gaily banded, living on the widely-separated leaves of Asclepias, with no attempt at concealment. The abundance of the imago of the Danais is then due quite as much to the immunity of the egg and larva from the attacks of parasites, as to any freedom it may itself enjoy from pursuit by insectivorous birds.

Although I have hunted butterflies for fifteen years, I confess I have never seen one in a bird's bill, and my faith in that method of lessening their numbers is very slight. Birds, too, must be their greater foes in earlier life; and the chances of living, which are certainly against them before they take wing, seem afterwards rather in their favour, at least, until they have accomplished their mission.

If, then, such an extraordinary element as Mimicry is to be summoned to the aid of Natural Selection, and can perform its task in such a masterly manner, why has it been made to waste its energies upon unimportant material? If the object of the resemblance be protection, why does not the unfortunate caterpillar of the Limenitis mimic the more favoured larva of the Danais?

I cannot now consult the writings of Messrs. Wallace and Bates, nor do I remember their statements respecting the abundance of the mimetic species compared to that of its normal congeners. In my own country *Limenitis Misippus* is, as a general rule, more common than *L. Ursula*, but the difference in their numbers is not very marked. It is by no means as great as one would expect had Mimicry in the imago state so strong a protective power as has been assumed. Two closely allied species,* occupying the same geographical area, do not often occur in the same abundance, whatever be the cause; and the disparity in numbers in these two species of Limenitis is no greater than occurs in many instances where mimicry plays no part.

Cairo, Egypt, Nov. 9 SAMUEL H. SCUDDER

Nepenthes

THE allusion to Nepenthes in Mr. Buckton's interesting article in a late number of NATURE, on the liquid secreted by this and other plants, prompts me to place on record a few facts regarding that genus, at which I have just arrived, after monographing the Pitcher-plants for the "Prodromus Systematis Vegetabilium" of De Candolle; a work of which the publication is suspended, owing to the siege of Paris.

The genus *Nepenthes* extends from Madagascar on the west to N.E. Australia, the Louisiade Archipelago, and New Caledonia on the east; embracing within these limits, thirty species, most of which have well-marked characters in the pitcher, but which, with only two exceptions, present a wonderful uniformity in the structure of both flower and fruit. It has two foci of maximum development; the Malay Peninsula (including Sumatra), and Borneo, in both of which localities the species are not only more numerous, but more gigantic than in any other country. No fewer than twenty-one species inhabit these two countries, of which thirteen are common to both; but, what is very remarkable, the intervening island of Java contains but one representative of the genus, and that a totally different species from either the Bornean or the Malayan; thus confirming the fact first brought to light by the Dutch naturalists, of the close biological relationship between the two former localities, to the exclusion of Java. Only one species has a wide range, the *N. phyllamphora*, which extends from Sumatra to Borneo, Amboyna, China, &c., but is absent from the island of Java.

Proceeding from the Malayan islands westwards, we find one species in east Bengal, more allied to the Javanese than to any other; another in Ceylon, the old *N. destillatoria* of Linnæus (a name long usurped in our gardens by the Bengal plant), which presents the first departure from the typical structure of the genus, having a spreading paniculate inflorescence; a character shared by those in Madagascar and the Seychelles. Proceeding further west to the African islands, we find still further deviations from the type, which now extend to the structure of the seed and

* *L. Misippus* and *L. Ursula* can with difficulty be separated in their earlier stages, although so unlike in their perfect forms.

fruit; for whereas all the eastern species have very long appendages to the seed, which are no doubt instrumental in its dispersion, these appendages are very short in the Madagascar species, and are wholly absent in the Seychelle one; which thus presents a case analogous to that of the prevalence of wingless insects on oceanic islets. Lastly, the Seychelle Islands species further differs from all others in the structure of its ovary and capsule.

To sum up, deviation from the type of the genus commences on the western confines of the principal centre of its distribution, namely in Ceylon; and the initial deviation, that met with in the Ceylon species, is the slightest, but is propagated (so to speak) westwards, equally characterising the two African islands Pitcher-plants, which again deviate still further from the type; the maximum deviation, however occurs, not in the great sub-continental Island of Madagascar, where the endemic species has a considerable range; but in the very small oceanic Archipelago of the Seychelles, where the only native species is confined to the one mountain summit of one island of the group!

The only other fact that struck me as bearing upon this subject of distribution is, that though present in the Seychelles, the genus Nepenthes is absent from the Mascarene group (Mauritius, Bourbon, and Rodrigues). This is only one instance of the broad distinction that exists between the vegetation of these Archipelagos, and which is in some way connected with the fact that the Mascarene group is volcanic, the Seychelles group formed of granite and quartz. Coincident and perhaps co-ordinate with these phenomena of plant distribution, geographical position, and geological structure, are the facts that the flora of the Seychelle Archipelago is more Asiatic, and the florulæ of its several islets very uniform; whilst the florulæ of the islets of the Mascarene Archipelago differ wonderfully, and in their totality are more African than Indian. The flora of the Mascarene group may hence be regarded either as a very ancient outlying province of the African, or as consisting of a more modern assemblage of plants, derived at various periods from Africa, but subsequently much altered by causes operating in the several islets; or more probably its peculiarities are attributable to both causes. Long as the Mascarene and Seychelle islets have been colonised, under Dutch, French, and English rule, their floras are still very imperfectly known; so much, however, of Mascarene botany is known, as to show that its relations with those of the Seychelle group and Madagascar, and the relations of all these with India and Africa, are most complicated, and present one of the most puzzling problems in Phytogeographical Science.

Royal Gardens, Kew, Dec. 18 J. D. HOOKER

THE author of the notice which appeared in a recent Number of NATURE is probably unaware that a minute analysis of the "water" found in the pitcher of Nepenthes was made a few years since by Dr. Völcker. For full particulars I will refer your correspondent to "Annals and Magazine of Natural History," 27, 4, 128, and "Phil. Magazine," 3, xxxv., 192; but I may perhaps be allowed to give the results of the analysis. My extract is from Liebig and Kopp's "Annual Report, &c." "The liquid was generally clear and colourless, rarely yellowish, and reddened litmus. That which was collected from different plants gave respectively 0·92, 0·91, 0·87, 0·58, 0·62, and 0·27, per cent. of residue, which contained in 100 parts 38·61 per cent. of organic matter, consisting chiefly of malic acid with a little citric acid, 50·02 of chloride of potassium, 6·36 soda, 2·59 lime, 2·59 magnesia."

During the early part of the present year I was led to suspect the presence of some form of tanno-gallic acid in the tissue of the stalk, and the kindness of a chemical friend enabled me to verify my conclusions; but no quantitative analysis has, to my, knowledge, been made beyond the one I have referred to.

Hull, Dec. 1 H. POCKLINGTON

Cockroaches

THE facts mentioned by your correspondent, Mr. Arthur Nicols (in your number of Dec. 8), are notorious to all West Indians. A friend of mine was marked for life by these things on board a ship coming home from Jamaica.

As for their scent, if you crush one in England it smells evil enough; and I don't doubt Aristophanes's sharp Greek nose had found that out. I have known bread, &c., in the West Indies uneatable from being run over by the small dark Cockroach of England, *Blatta orientalis;* while the great pale species, *B. occidentalis*, is utterly unbearable. C. KINGSLEY

EARED SEALS AND THEIR HABITS*

THIS paper, which forms the first number of the second volume of the "Bulletin of the Museum of Comparative Zoology at Harvard College in (Transatlantic) Cambridge," is one of great zoological importance, and likewise of much general interest. The Eared Seals, a group of marine Carnivora, which form a well-marked division of the Pinnipedia, distinguished by the possession of a small external ear-conch and other peculiarities, are still very imperfectly known, although of late years they have attracted the attention of several eminent naturalists. Unfortunately, however, the great variations which occur in the sexes and different ages of these animals, have not been sufficiently appreciated by those who have studied the few specimens of them preserved in European museums. The consequence has been that numerous artificial species have been manufactured upon stray skulls and imperfect skins, which have exhibited what were really only individual differences. Moreover, what is worse than this, under the prevailing mania for coining new generic names, more genera of Eared Seals have been established than the number of species which actually exist in nature. Foremost amongst these offenders, we regret to say, has been one of our own countrymen, who, in a recent article published in the "Annals of Natural History," has subdivided, on the most trivial characters, the family *Otariidæ* into four subfamilies and ten genera! We shall see how much more reasonable and consonant with nature are Mr. Allen's views on the arrangement of these animals.

Mr. Allen commences his paper by an Introduction, in which he discusses at some length the writings of preceding authors on this subject. He then proceeds to set forth his own views, distinguishing first of all the Eared Seals from the two other families of the Pinnipedia (the true seals and the walrus), and afterwards the different genera and species of *Otariidæ*, in a very neat and perspicuous manner. Mr. Allen is only able to recognise eight species of these animals, and considers two of these rather doubtful. Four of them belong to the "Hair-seals," or "Sea-lions," which have no under fur, and four to the smaller "Fur-seals," or "Sea-bears," which have a dense under coat, and furnish the seal-skin cloaks so much now in fashion with English ladies. The well-known "Sea-lion" in the Zoological Gardens belongs to the former group—being a female of the Southern Sea-lion (*Otaria jubata*).

Mr. Allen next begins to treat at great length of the North Pacific species of Eared Seals, of which he is able to give us a full and excellent account from the specimens in the Museum to which he is attached, together with those in other American collections. These North Pacific species are the Steller's Sea-lion (*Eumetopias Stelleri*), Gillespie's Hair seal (*Zalophus Gillespii*), and the Northern Fur-seal (*Callorhinus ursinus*). Of these three animals such full particulars are given that it seems scarcely possible that there can be any more confusion respecting them. But the most remarkable part of the present memoir is perhaps the account of the extraordinary habits and customs of the Northern Fur-seal, given from Captain Bryant's observations of these animals, on the Pribyloff Islands, off the Northern part of Alaska Territory. As is the case in other known species of Eared-Seals, there is an enormous discrepancy in the size and weight of the two sexes, the weight of the female being rarely more than one-fourth of that of the full-grown male.

The Fur-seals resort to the Pribyloff Islands during the summer months for the purpose of breeding, and in St. Paul's Island, where Captain Bryant made his obser-

* "On the Eared Seals (*Otariadæ*), with detailed Descriptions of the North Pacific Species." By J. A. Allen. Together with an Account of the Habits of the Northern Fur Seal (*Callorhinus ursinus*). By Charles Bryant. With Three Plates. 8vo. 108 pp. (Cambridge: University Press. 1870.)

vations, occupy at this season a belt of loose rocks along the shore, varying in width from five to forty rods. Twelve miles of shore line at least are taken up by what is called their "*breeding rookeries*" in this island, and are tenanted by not less than 1,152,000 breeding males and females, according to Captain Bryant's estimate. Each male seal stations himself in a particular spot, usually the same as he has occupied in former years, and keeps about a square rod of ground free around him to afford space for the reception of his ten or fifteen wives. By the 15th of June all the males have arrived, and have stationed themselves each in his own domain, not without constant growlings and fightings with his neighbours for what he considers the best station. The young males are not allowed to take a place in the "rookeries," but are driven by the patriarchs back into the sea, or compelled to resort to the high rocks above. After the middle of June, the females arrive; in small numbers at first, but increasing as the season advances, until the middle of July, by which time they are so crowded together that they often overlap one another. The old males who are nearest the shore seize upon the females at once, and of course fill their harems first. But the males who are higher up on the rocks select the time when their more fortunate neighbours are off guard to steal their wives, taking them up in their mouths, and carefully carrying them off to their own dominions, as a cat would her kittens. Struggles often occur between two males for the possession of the same female, and both seizing her at once, terribly lacerate her with their teeth. When his harem is full, the old male struts complacently around reviewing his domestic circle, and fiercely driving off all intruders. Two or three days after landing and taking up her abode, the female brings forth her single pup, after which she is ready to associate with the male. By the middle of August the young are all born, and the females are again pregnant. The old males having been constantly in their stations for four months *without food*, now leave the females and young to the company of the younger males, and go off-shore to feed. At the end of October the whole body of seals leave the island and journey southwards.

The greatest care is taken by the hunters never to disturb the breeding places of the seals in any way, and the only seals killed for the sake of their fur are the younger animals (principally males) that resort to the higher rocks above the rookeries to pass the night. A party of men armed with clubs surround a portion of the herd and drive them off sometimes six or seven miles across the island, to the place selected for killing and skinning them. By this plan the rookeries are less liable to be alarmed, and the seals are made to carry their own skins to the salting houses, which would otherwise be a work of much labour. At the present time the annual yield of seal-skins from the Pribyloff Islands is estimated to have reached 100,000, and the killing yearly of this number is believed in no way to check their increase, but rather to augment it.

This short sketch will serve to give an idea of Captain Bryant's account of the extraordinary habits of this animal, and of the way in which the large annual supply of the much-valued seal-skin coats of civilised life is produced. Many other details of the highest interest are added, for which we must refer our readers to the original article. Although several accounts have been already published of the habits of other species of this group, none, we believe, is so full and perfect as the present, which forms a valuable appendix to Mr. Allen's excellent essay already spoken of. In short, it may be truly said that, by this single memoir, more extensive knowledge has been gained concerning this little-known group of mammals than by the half-dozen different systems of arrangement of them which have lately emanated from the British Museum, and the publication of an indefinite number of (so-called) new genera and species founded upon stray skulls and imperfect skins.

P. L. S.

SCIENTIFIC TEACHING IN ELEMENTARY SCHOOLS

THE following address, signed by Prof. Huxley, as President of the British Association, has been presented to the Vice-President of the Council by a deputation, consisting of the President of the Association, the General Secretaries, and the Treasurer; Sir Charles Lyell, Bart.; Sir John Lubbock, Bart., M.P.; Dr. Lyon Playfair, M.P.; and Mr. Francis Galton:—

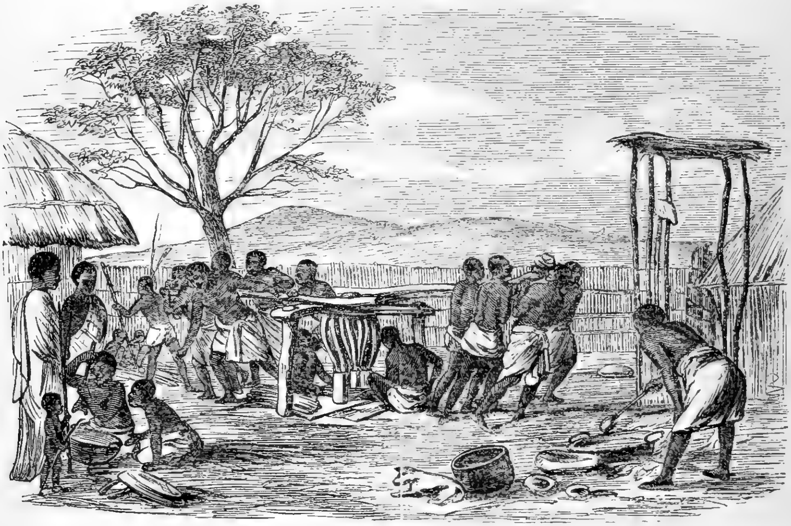
"The deputation from the Council of the British Association for the Advancement of Science waits upon you for the purpose of urging the advisability of including elementary Natural Science among the subjects for which payments are to be made under the authority of the Revised Code. We have asked you to receive us at the present time because we understand that you have announced your intention of making certain modifications in the Code. Our reasons for requesting you to give direct encouragement to the teaching of Natural Science in elementary schools are three. Firstly, we conceive such teaching to be one of the best instruments of education in the sense of intellectual discipline, and in many respects better calculated to awaken intellectual activity than other studies; secondly, we think that a knowledge of the elements of Natural Science has a high value as information; and thirdly, we are of opinion that scientific training and teaching in the elementary schools will afford the best possible preparation for that technical education of the working classes which has become indispensably necessary to the industrial progress of the country.

"We take the liberty of pointing out to you that, in asking for the introduction of scientific teaching into the elementary schools, we are not seeking for the creation of a new system or even of new executive machinery. The Science and Art Department does already provide for elementary scientific instruction; and all that is necessary to fulfil our desire is, that the system of the Science and Art Department and that of the Revised Code shall be brought into harmonious co-operation. In preferring the request that instruction in the elements of Science shall be made part of the regular course of instruction of all elementary schools, we desire carefully to guard against the supposition that we are seeking for such an amount of this kind of instruction as would interfere with the teaching of reading, writing, and arithmetic, and the other essential constituents of primary education. On the contrary, we think it very desirable that systematic instruction in elementary Science should be given only to those scholars who are able to read and write fairly; that it should be limited to certain well-defined subjects, such for example as elementary physical geography, elementary physics and chemistry, elementary botany, and, in consequence of its relation to the public health, elementary human physiology; and that care should be taken to make the instruction, so far as may be, real and practical.

"Finally, we desire to point out that such scientific instruction in the elementary schools as we pray for, would afford a means by which any child of exceptional aptitude for scientific pursuits might obtain the education suited to its capacity in the higher schools, and that in this way advantages similar to those which are offered by the scholarships and exhibitions of grammar-schools to the children of the well-to-do classes of society, would be extended to the poor and necessitous. In other countries in which well-organised systems of secondary education for the working classes exist, it has been found necessary to give a taste for Science in the elementary schools, so that the youth of the country may be induced to take advantage of the more advanced schools. While, therefore, we look with pleasure to the introduction of Science into the endowed schools of the country, we still believe that it will be necessary to link them to the elementary schools by commencing instruction in Science in the latter,"

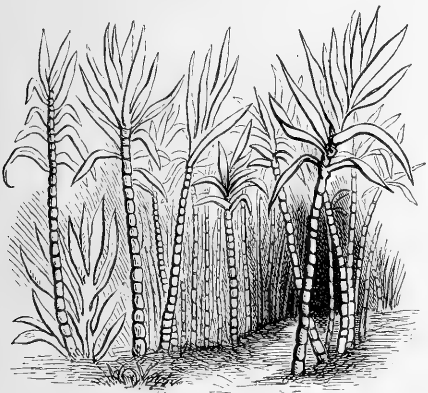
SUGAR

IN considering the subject of sugar, its produce, supply, uses, and adulteration, we enter upon a much wider field of inquiry than in either of our former articles, though the present has an intimate connection with our previous subjects; for neither coffee, tea, nor cocoa is usually considered properly prepared for table without the addition of sugar; it is used more or less in every part of the globe, for in the widest sense of the word, sugar is contained in most vegetable juices, indeed it is the principal food of young plants. In the rising sap of some trees in spring it is very abundant, as well as in the young stems of grasses. The starch stored up in many seeds at the time of germination is converted into sugar. The process of malting consists in forcing the seeds of the barley to germinate, and just at the time when most sugar is found, to stop their growth, so that the sugar is preserved for our use and not consumed by the growing plants. Sugar is extracted for the use of man from many distinct plants. Chemically considered, there are two kinds of sugar; one called cane sugar, which is obtained from the sugar-cane, the beet-root, the maple, &c.; the other called grape sugar, or glucose, which is chiefly found in grapes and various fruits. The bulk of the sugar used in this country is the juice of the sugar-cane (*Saccharum officinarum*, and perhaps allied species), a gigantic perennial grass, growing usually ten or twelve feet high, but in some situations attaining fifteen or sixteen feet; it has a jointed stem, somewhat similar to that of the bamboo, the upper part having a series of long, narrow leaves, and the flowers produced in large, feathery panicles. Some doubt exists as to the true native country of the sugar-cane, though it is not at all improbable that it came from Southern China and India. The plant is now very extensively cultivated in the East and West Indies, China, the Mauritius, S. America, and other parts.



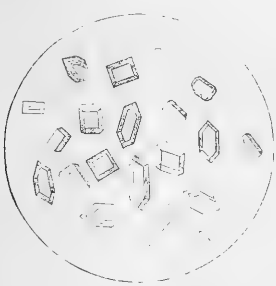
SUGAR MANUFACTURE AT KATIPO, A VILLAGE IN EASTERN TROPICAL AFRICA

The use of sugar dates back to a remote age; its introduction into Europe is said to have taken place in the 9th century, when it was brought from the East into Sicily by the Saracens, and the first European plantations were established about 200 years later in Sicily and Valentia. In the early part of the 15th century its cultivation began in Madeira, the Canary Islands, Granada, &c.; and at the close of the same century Columbus introduced it into one of the West Indian Islands. Barbadoes sent large quantities of sugar into England so long ago as 1646. The sugar-cane does not ripen its seeds, and is, therefore, propagated by cuttings. The canes after planting require, according to the situation and soil in which they are grown, from ten to twelve, or even twenty months before they are ready for cutting; they are taken off near the base, and the stem is then divided into equal lengths, put up into bundles, and carried to the mill. These lengths are submitted to pressure between heavy rollers, by which the saccharine juice is squeezed out, and is collected in a cistern; it is next filtered and clarified, and the feculent matters separated by lime, a rapid system of boiling now throws off the watery particles by evaporation; and the sugar is brought to such a thickness or consistency that after boiling in one pan, its bulk is so reduced that it is removed to a smaller or medium sized pan, where it is boiled again and skimmed until it is reduced to sufficient bulk and thickness to enable it to undergo a similar operation in the next, or smallest size pan, where it is again boiled till it has assumed the consistency of a thick syrup, which partially granulates upon cooling. It is, however, still in the form of a soft mass, the crystallised portion being imbedded in a thick juice, which is known as molasses. To remove this the whole mass is put into loosely made casks or hogsheads, through which the molasses drains, leaving the crystallised portion more or less dry. After being kept a few weeks, during which time molasses continues to drain from it, it is packed in bags or hogsheads, and is ready for shipment. In this state it is known as raw, brown, or Muscovado sugar. The process of extracting and preparing the juice for export is not exactly similar in all countries; though the principle is the same, the practice varies according to the amount of intelligence brought to bear upon it.



FIELD OF SUGAR CANE

The drawing on the opposite page, which has been copied by permission of Mr. T. Baines from one of his paintings in the Kew Museum, represents the whole process of sugar making at a village in Eastern Tropical Africa. Under the tree, in the left-hand corner, is a native cutting the cane into lengths, and others collecting them into bundles which are afterwards passed between the rollers of the press, as seen in the centre of the picture. Boiling and crystallisation are shown in the right and left hand corners respectively.



SUGAR CRYSTALS MAGNIFIED

The quantity of saccharine matter contained in the cane varies according to the nature of the soil, climate, or other conditions under which the plants are grown. An acre of land under sugar cultivation may yield from one up to four tons of sugar, and from each ton of sugar after the first process of crystallisation somewhere about seventy gallons of molasses will drain; so that when we consider the labour required to keep a sugar plantation in full working order, such as tending the plants, expressing the juice, evaporation, crystallisation, and the subsequent waste both of sugar and molasses, as well in the draining on the voyage home, as during the time of its storage in the docks, and above all, the duty demanded upon sugar by the British Government, it does seem rather surprising that the article can be retailed at the price it is, though many are apt to call out that it is not so cheap as it ought to be. Sugar in its most common use cannot now be considered a luxury; to rich and poor alike it has become a necessity, indeed, amongst the lower classes a larger proportion is consumed than amongst the middle and upper section of the community, the average annual consumption per head of the whole population of the United Kingdom being about forty pounds. The East and West Indies, Mauritius, and Brazil now supply the bulk of the sugar brought into the English Market. It is imported in hogsheads and bags, the latter vary much in size and the sugar is also of various qualities, some of it indeed as it arrives has much the appearance of black muddy gravel or sand; most of this undergoes a further process of purification and recrystallisation in our own sugar refineries, which abound at the East end of London, as well as at Greenock, Glasgow, Liverpool, and Manchester. From these refineries the sugar comes out in the forms known in trade as lump or loaf sugar, crushed lump, pieces, and bastards.

The quantity of unrefined sugar entered for home consumption during the year 1869 was 11,188,081 cwts., and this exclusive of 1,025,929 cwts. of refined sugar and sugar candy, and 741,771 cwts. of molasses. The sugars best known in the British grocery trade are Demerara, Berbice, Barbadoes, Porto Rico, and Mauritius. These are sufficiently refined and crystallised in the colonies producing them as to suit the requirements of the retail trade. Those from Antigua, Cuba, Madras, Penang, &c., usually find their way into the hands of the refiners, brewers, and confectioners. Molasses is, as we have before said, the drainings from raw cane sugar. It is used for many purposes; large quantities of rum are distilled from it, often on the plantation where the sugar is produced; and where it is not so used it is exported, the sugar refiners in England buy it up largely, and produce a quantity of crystallised sugar from it. Rum, however, is usually made from the skimmings taken from the last boiling of sugar, which are mixed with proportionate quantities of molasses and water. Though molasses and treacle are often spoken of as identical, they appear to be different in their origin, for while the former is the drainings of raw sugar, the latter is the drainings of refined sugar. We have hitherto spoken only of cane sugar, or, to speak more correctly, of that obtained from the sugar-cane, but a large portion, indeed the bulk, of the sugar used on the Continent, is obtained from the beet-root (*Beta vulgaris*), the manufacture of which forms a separate article of industry.

JOHN R. JACKSON

NOTES

INTELLIGENCE has been received of an accident which occurred to H.M.S. *Psyche*, carrying the Sicilian section of the Eclipse Expedition from Naples to Catania; but, we are happy to announce, without injury to any of the passengers or crew, or loss of any of the instruments. The following are all the telegrams to hand at the moment of going to press:—"The *Psyche*, with the Eclipse Expedition on board, has struck on a sunken rock near Catania. All hands have been saved, and also the scientific instruments. The captain, who has behaved most nobly, is still on board, and, with a view to save the ship, has telegraphed to Malta for assistance." The following telegram has been received at the Admiralty:—"*Pysche* has struck, while running by chart, on a sunken rock near Catania. All saved. Instruments sent into Catania. Commander Fellowes has acted nobly, and hopes to save ship, if assistance comes at once from Malta, where he has telegraphed. *Royal Oak* sent for." We may congratulate ourselves that the expedition was in the hands of trained men belonging to one of Her Majesty's ships. We learn that nothing has occurred which need in the least imperil its success, and t ust that even the ladies of the party will have suffered nothing worse than temporary inconvenience and alarm.

MR. J. R. HIND, writing to the *Times*, states that, although the Eclipse of the Sun, which takes place to-day, will have been exceeded in magnitude by more than one of the eclipses which have been visible in this country during the last thirty years, it will yet be the greatest eclipse that can be witnessed in England during the remaining thirty years of the present century, and on this account possesses a degree of interest which does not always attach to partial eclipses. If we take successive intervals of thirty years, commencing with 1781, and note only those eclipses visible in London, in which the moon has covered more than half the sun's diameter, we find between 1781 and 1810 two eclipses, between 1811 and 1840 six eclipses, between 1841 and 1870 seven eclipses, while between 1871 and 1900 there will be one eclipse only of similar magnitude. This single eclipse in the ensuing interval of thirty years will not occur until the last year of the century, or till the 28th of May, 1900, and the magnitude will not then quite reach 0 7 of the sun's diameter. The next solar eclipse visible in England is a small one on the morning of May 26, 1873.

THE French Eclipse Expedition may not have proved a failure, as has been feared. We have received intelligence from Paris that on the 1st December M. Janssen left in a balloon, assisted by a sailor. No letter was given him in order to prevent the Prussians detaining him as a prisoner of war. A balloon reached Brittany about that time, and was styled a private balloon. Telegrams and notices were sent to France from Mr. Lockyer, to invite M. Janssen to join the English Eclipse Expedition, but it appears that none of these communications have reached him, owing to the interruption of regular postal telegraphic service in France. M. Janssen was intending to proceed to Medeah, an Algerine town.

SOME time ago we announced that Sir Roderick Murchison had offered the munificent sum of 6,000*l*. for the endowment of a Chair of Geology and Mineralogy in the University of Edinburgh, on the understanding that the annual proceeds of this sum would be supplemented by a grant from Parliament. We are happy to state that Government has consented to this proposal, and has agreed to recommend an annual grant of 200*l*. This desirable result (for which the University, we believe, is largely indebted to the earnest co operation of its member, Dr. Lyon Playfair) will be welcomed as another evidence that our authorities are not so indifferent as they have been supposed to be to the claims of scientific education.

DR. HUREAU DE VILLENEUVE, secretary to the French Aëronautical Society, and editor to the *Aeronaut*, a paper devoted specially to aëronautics, has established at his residence an ambulance for aëronauts. He had to attend to a few cases from accidents of different descriptions in the management of captive balloons, and fewer of soldiers who had drawn the ropes for their aërial observations. M. de Villeneuve is to open a regular course of lectures on aëronautics at the Petite Sorbonne. It is the third time that a regular course of lectures has been delivered in Paris on this subject: the first time by Dupuis Delcourt, at the Athénée about forty-five years ago, when Comte was delivering his lectures on Positive Philosophy; the second time by M. W. de Fonvielle, at the Lecture Hall of the Boulevard de Capucines, three years ago.

THE new Meteorological Observatory established by the city of Paris in the well-known Palais du Bey de Tunis, which was a part of the great Champ de Mars Exhibition, is no longer in operation. It was put into requisition to be used as a barracks. M. Sainte-Claire Deville, the elder, who was the director, has protested against such a requisition, but his protest was wholly disregarded.

M. MARIE DAVY is now in Paris, and engaged in meteorological observations, as well as M. Chapelas Coulvier Gravier, who keeps his watch from the Luxemburg Palace for falling stars. He publishes regularly the records of the observations in the *Comptes Rendus* and the *Journal Officiel*. He has published a description of several magnificent auroral displays, which were described by several witnesses in different papers.

A VERY influentially-signed memorial from heads of houses, professors, tutors, lecturers, and fellows of colleges in the University of Cambridge, has just been sent to the Lord President of the Committee of Privy Council on Education. The memorial prays that women may be appointed to the office of Inspector of Schools, and points out some of their qualifications for that responsible office. The memorial is signed by seventy-two resident graduates, all of whom are fellows of colleges or hold college or university offices in the University of Cambridge. Among those who sign are the Vice-chancellor and five other heads of houses, including the Masters of Trinity and St. John's; nine university professors; the senior tutors of every college, with three exceptions; all the tutors, assistant tutors, and lecturers of Trinity College, with two exceptions; and of the remainder all except eight are engaged officially in teaching in the Colleges or University.

THE death is announced, in his seventy-first year, of the Rev. Joseph Bancroft Reade, President of the Royal Microscopical Society. He was educated at Caius College, Cambridge, where he took his B.A. degree in 1825, when he was thirty-sixth senior optime in the mathematical tripos. In 1839 he was presented by the Royal Astronomical Society to the vicarage of Stone, near Aylesbury, and at the time of his death was rector of Bishopsbourne, near Canterbury.

WE shall be much obliged to any of our correspondents who will oblige us (for the purpose of drawing up a tabular account) with particulars of any hitherto unrecorded meteorological phenomena which may have occurred during the present year, as auroras, earthquakes, large sun-spots, meteors, storms, volcanic eruptions, haloes, &c. Similar information will be very acceptable from the continent of Europe, America, or the Southern Hemisphere.

THE Royal Horticultural Society has been compelled, by the pressure on its funds, to dispose of a portion of its gardens at Chiswick, the most valuable portion of its property in a scientific point of view. Among the articles sold were a number of fine trees, Pyramid Pears, Dwarf and Trained Apples, Filberts, Wellingtonias, Cupressus, Piceas, Araucarias, &c., in all no less than 12,757 plants, fetching about 600*l*. The portion of the Gardens which still remains covers about 33 acres; and the orchard will be reorganised on a smaller scale, and the trials and experiments, practical and scientific, will still be carried on. The Gardens were originally founded in 1821.

THE galleries of the Royal Albert Hall, which are to be used for the display of architectural drawings and models in the forthcoming International Exhibition of 1871, are approaching completion. Architects have been invited to inspect the Hall, and to see the galleries appropriated to their works, on Wednesday, December 21, at 11.30 A.M. Some trials of the acoustic properties of the building were to be made between 12 and 12.30.

THE *Journal of the Society of Arts* states that the Council of the Society has sanctioned a plan for establishing a National Training School of Music. For promoting this purpose it is proposed that a musical section of the society be instituted, with a separate fund, in order to give concerts annually in the Royal Albert Hall; these concerts to consist of vocal and instrumental music of the highest character. After paying the expenses of the concerts, the profits are to be applied to the establishment of a National Training School for Music.

THE Perthshire Society of Natural Science proposes starting a Quarterly Magazine, to be called the *Scottish Naturalist, and Journal of the Perthshire Society of Natural History*. It will be specially devoted to recording observations and discoveries made in the northern part of this island; and it is intended that it shall contain (in addition to the "Proceedings" of the Society), reports of the meetings of Scottish Natural History Societies; a record of Scottish captures; observations and discoveries both zoological and botanical; scientific jottings; notes and queries; lists of species for distribution in exchange, &c. As the carrying out of this scheme depends entirely upon the encouragement and support received by the Society, it is hoped that those interested will at once send in their names as subscribers to the honorary secretary, Mr. A. T. Scott, Clydesdale Bank, Perth.

THE *Saturday Review* of December 10 refers to "the gigantic Lycoperdon, or Puff-ball, which in one night acquires the bulk *of a child of ten years old*, and produces about 96,000,000 cells a minute!" We have both seen and heard of Puff-balls as large as a child's *head*, but one of this "bulk" is, we imagine, somewhat rare.

THE Folkestone Natural History Society has issued the following programme of its proceedings for the present (its third) winter session:—Nov. 8: Public lecture on "Solar Eclipses," Rev. C. L. Acland, M.A. Nov. 23: Microscopical Conversazione. Dec. 13: Public lecture on "Food, and the Process of Digestion," F. Fagge, Esq., F.L.S. Jan. 10: Public lecture on "Fossils and their Teachings," Henry Ullyett, hon. sec. Feb. 1: Annual meeting. Feb. 7: Public lecture on "The Natural History of Language," by W. J. Jeaffreson, Esq., M.A. Feb. 22: Ordinary meeting, paper, and discussion. March 7: Public lecture on "Iceland and Spitzbergen," by C. E. Fitzgerald, Esq., M.D., president. March 22: Ordinary meeting, paper on antiquities, and discussion. March 28: Public lecture on "The Materials for Antiquarian Research in S. E. Kent," by the Rev. Canon Jenkins. A class in Botany is held every Wednesday, at 4 P.M., by the Rev. C. L. Acland, and one in Geology every Monday at 8 P.M., by Mr. Ullyett. The Museum is open free on Thursday evenings and Saturday afternoons, as well as on the occasion of meetings; and a library of reference is in course of formation.

MR. EDWIN C. REED has been employed by the Director of the Museum of Santiago, in Chili, to arrange the insects. He has classified the foreign insects, which had hitherto remained unpacked. Mr. Reed is preparing a Chilian collection to send to California in exchange for a collection from that country.

THE United States Government commenced on the 1st of November the publication of a daily record of the state of the weather in various parts of the country. The following extract from the *New York Journal of Commerce*, dated Nov. 5th, shows the view entertained in the States on this subject:—"The Federal Government has lately done one thing which men of all parties will agree in commending heartily. It has made arrangements to furnish daily reports of the markings of the barometer and thermometer, the direction, velocity, pressure, and force of the wind, and the state of the weather, at points in different parts of the country. The shipowner, master, or merchant, reading this journal, has before him every day trustworthy advices of the weather all over the United States only a few hours old, and sufficiently fresh to apprise him of the danger or safety of sailing or making shipments from this port. Much depends on the accuracy of the reports, and for that we find good assurance in the fact that they are prepared by army officers, most of whom have received an education scientific and practical enough to qualify them for the work. The Associated Press have made an appropriation to have an observer among the party who will watch through the winter on the top of Mount Washington, White Mountains. From that point also we expect to receive daily bulletins, which will not only be serviceable to commerce, but in our coldest weather here may make people more comfortable to think how much colder it is away up on that windy peak. Prof. Hitchcock will be in charge of the party, which comprises a number of able scientists. The Chamber of Commerce is making a move to supplement the action of the Government at this point with a little more money." The places at present contributing "weather reports" are Augusta (Ga.), Boston, Buffalo, Cleveland, Cincinnati, Chicago, Cheyenne, Detroit, Duluth, Lake City (Fl.), Milwaukie, Montgomery, Mobile, Nashville, New Orleans, New York, Oswego, Omaha, Rochester, St. Paul, St. Louis, Toledo, and Washington.

A ST. PATRICK, says the *Pall Mall Gazette*, is evidently wanted in India as much as ever he was in Ireland. During the year 1869 no fewer than 11,416 persons in the Bengal Presidency died from the effects of snake bite. The return giving us this information has been carefully compiled; all the merely sick and wounded have been omitted, as well as those sudden deaths which in India are often attributed to snake-bites by heirs to property unduly eager for their inheritance. Such a mortality from such a cause is sufficiently startling to the sophisticated mind of a stay-at-home Englishman, but the more surprising fact remains that this destruction of human life goes on year by year, and that no efficacious means are adopted to check its ravages.

The *Pall Mall Gazette* states that we owe our supplies of Indian cotton to the American war, and we may have to refer the cultivation of tobacco in our colonies to the present campaign. A good deal of the leaf employed in the manufacture of cut tobacco comes to us from the Continent, and of course that source is now closed; but the smoker may be consoled by hearing that India, Jamaica, and Natal are all engaged in cultivating the plant. Latakia from the West Indies has been received in London and reported upon favourably, and the samples of tobacco from Natal are said to be remarkably good. What the Indian Government has already done for the cultivation of tea, cinchona, and ipecacuanha, it is now doing for the tobacco plant. Seeds of the best varieties have been distributed in suitable districts, and the time may speedily come when the Bengal cheroot may be a production of the Presidency.

FROM the report of the cotton department of India it seems that the crops in the several districts have, during the past year, yielded a satisfactory return. We also learn that a very extensive system of adulteration exists by mixing two or more qualities in one bale, to which a stamp, indicating a superior quality, is affixed. With regard to the use of English ploughs which have been introduced, it is said that "the cohesion and tenacity of the richer black cotton soils are evidenced by the manner in which they get rent and cracked into deep fissures instead of becoming pulverised by the rapid contraction they undergo when exposed to the fierce rays of the sun after the crops have been removed, and from the same cause the upper surface becomes baked and hardened into a crust, which is about as inaccessible to the plough as if it were a pavement. The cultivator has accordingly to wait until the advent of the monsoon has softened and removed this crusty impediment, and, if it should happen that the first crusts are very heavy and continuous, he is still further delayed from an opposite cause, namely, on account of his fields having become too soft for his cattle to move on, so that he has to wait for a favourable break to get rid of the surface moisture." In this state of the land the plough gets clogged, and the animals have not strength to move the instrument, so that "both ploughs and ploughmen succumb, and the antediluvian implement of the ryot is found to be the only feasible one."

SOME idea of the damage done to vegetation by locusts in tropical countries may be gathered from the following account of a raid made by them in an East Indian cotton plantation. The means adopted to repel them was by recourse to the discordant sounds of native music—horns, tom-toms, and pipes—aided by the waving of flags and branches of trees. These measures, undoubtedly, saved the produce; for, judging by the performance of the very small number that succeeded in gaining admission to one of the finest fields unobserved, had a full complement effected a lodgment, one hour would have sufficed to strip every tree of its leaves, though the foliage was abundant, and the plants in one field from five to six feet high. The immunity which the native Indian cotton enjoyed from the attacks was considerable, considering the avidity with which they devoured the exotic descriptions, and, true to their early traditions, the Egyptian was evidently an especial favourite. Some of the swarms that passed over the country at that time were exceedingly numerous. The arrival and settlement of one mighty mass was a remarkable sight. What was first observed was a sort of haze on the verge of the horizon, in a long line, as if a steamer had passed, and its smoke was rising into vapour; this was some hours before the insects arrived. The cloud gradually thickened, and rose higher as they approached. When they got fairly overhead the air became darkened as if night was setting in, it being yet mid-day, and the peculiar sound which accompanied their flight resembled that of the rustling of the leaves of the peepul tree when agitated by light winds; but it is not until they have settled down that any idea can be formed of the immensity of their numbers, and the early dawn, before sunrise has warmed them into life and motion, is the time to witness this most extraordinary sight. In the instance now referred to the appearance the face of the country wore would be best described by supposing that a tolerably heavy fall of snow had taken place, only that the colour of it was a light brown, and this extended for miles, as far, indeed, as the eye could reach. Trees were favourite perching-ground for the night, and the manner in which they contrived to crowd upon them, piles over piles, concealing every vestige of leaf and branch, gave the trees a singular appearance. At one spot a stout and wide-spreading branch of a banyan tree had snapped at its stem from the incumbent weight of the insects.

RICH mines of gold and silver are being daily discovered in the State of Tulima, in Columbia, according to late advices.

A RECENT number of the American *Journal of Chemistry* contained the following story of the first introduction of the stereoscope to the *savants* of France. The Abbé Moigno took the instrument to Arago, and tried to interest him in it; but Arago unluckily had a defect of vision which made him see double, so that on looking into the stereoscope he saw only a medley of four pictures. The Abbé then went to Savart, but he was quite as incapable of appreciating the thing, for he had but one eye. Becquerel was next visited, but he was nearly blind, and consequently cared little for the new optical toy. The Abbé, not discouraged, called next upon Puillet, of the Conservatoire des Arts et Métiers. He was a good deal interested in the description of the apparatus, but unfortunately he squinted, and therefore could see nothing in it but a blurred mixture of images. Lastly, Biot was tried, but Biot was an earnest advocate of the corpuscular theory of light, and until he could be assured that the new contrivance did not contradict that theory, he *would* not see anything in it. Under the circumstances, the wonder is that the stereoscope ever got fairly into France.

MIMICRY AND HYBRIDISATION *

SOME time since I had occasion to study with care, for the purposes of a work on which I am engaged, the phenomena of mimetic analogy made known by Mr. Bates, which have lately formed the subject of discussion at the British Association, and in the pages of NATURE, in which I observe with pleasure that one of our body, Mr. A. W. Bennett, has borne an honourable part. Neither he nor any of the gentlemen who have written on the subject, have, however, so far as has come under my notice, brought the point to its real issue. They have accepted battle on the field on which Mr. Bates has placed it, and although they may have achieved a victory over him, they have not succeeded in rescuing the subject from its obscurity. He may be wrong without their being right. I am not surprised at their having been led to accept his premises; when I first approached the subject I did the same; but the longer I live and the more extended my experience becomes, the more surely do I find that when a theory looks shaky and unsound, the place to look for the flaw is not in the upper story, but in the basement. It is in the foundation that the crack will almost invariably be found. I am sure it is so here.

Mr. Bates found in the Valley of the Amazons a number of species of a Northern tribe of butterflies, wearing the colour and form of a Brazilian tribe, and so like in their varieties and strains that they obviously represent some different phenomenon from the ordinary one of mere difference in species. To account for this he devises a theory on the Natural Selection plan. The Brazilian tribe has a bad smell, and birds and insects of prey consequently do not feed upon them, and the Northern tribe, in the course of their variation in the dark, accidentally produce one something like the Brazilian one, which produces others in the same direction by Natural Selection, until the mimics are brought to perfection. Every inch of the ground he goes over here is mined and unsound—the bad smell has not been observed in North America where similar mimicry occurs—birds and insects of prey hunt by sight and not by smell, and the various communications on the subject in NATURE point out a variety of other insuperable objections. But my object is not so much to show that a friend and entomological brother has been seduced by a "bad smell" to go on a wrong scent, like a good dog after a red herring, but to find out the true explanation of the phenomenon.

The explanation seems to me to be simply Hybridisation; but before committing myself to it, as there were one or two points on which I was not sure how far the phenomena corresponded with those of hybridisation in plants, I applied to my friend Mr. Isaac Anderson Henry for information upon them, and he has sent me a paper (for the Scientific Committee of the Horticultural Society), as well as some other information, which enables me now to say that there is not a phase or a fact in the mimicry in question, for which I cannot produce the exact counterpart in the hybridisation of plants.

In the first place the mimicked and the mimickers are always found together, and even the mimickers of varieties are only found beside the varieties that they mimic. Now, it is plain that if the resemblances be due to hybridisation, it is inevitable that the two must always be found together, at least in the first instance. It may be that after the hybrids are established and advanced into the position of actual species, the species (*i.e.* the parent and offspring) might diverge from their primary locality, the one to the right and the other to the left, and so cease to be found together; but this must be an after act, and consequently an exception. The natural condition is to find both together, and so they are always found together. But this would not be the natural condition if the mimicry were produced by Natural Selection. The same enemies are found over thousand of miles, and the same kind of enemies over tens of thousands; and there is no advantage to be gained by mimicking one variety of Danais more than another. The same advantageous results would be obtained by mimicking in the east the form that prevails in the west, or in the north the form that prevails in the south, but the imitation of each variety is limited to the district which it inhabits, however narrow and restricted it may be. Natural Selection, therefore, fails entirely to account for the localisation of the mimickers of varieties.

In the next place the mimicked occur always in overwhelmingly greater numbers than the mimickers. Mr. Bates says:—"The Ithomiæ (Danaids) are all excessively numerous in

* This paper was originally presented to the Scientific Committee of the Horticultural Society (Dec. 7, 1870), but has not yet been published elsewhere.

individuals, swarms of each kind being found in the localities they inhabit. The Leptalidæ (mimics) are exceedingly rare; they cannot be more than 1 in 1,000 with regard to the Ithomiæ." This is quite what we should expect if the resemblance is due to hybridisation. Hybridisation is not the normal mode of producing either species or individuals. It is not the plan laid down by Nature. Being exceptional, it is, of course, comparatively rare. But there is no reason for rarity if it be the result of Natural Selection. That operation is going on equally upon all, and under that hypothesis mimicry is just as powerful an influence in modifying and producing forms as any other; and there is no reason whatever why it should have less conspicuous results; indeed, it should have more, if we judge by the long-continued persistence of influence which must have been in operation to produce such exact resemblances, and which, indeed, seems very much thrown away when confined to the 1 in a 1,000 mentioned by Mr. Bates.

Although mimicry occurs between various tribes or genera, it has been observed most frequently in connection with the most common species of the country. This is what would naturally be the case with hybridisation, supposing all to start fair and to be equally liable to hybridisation. But this is an assumption which we are scarcely warranted in making, and I therefore do not press this inference further than as of some conditional value.

After the second generation of hybrids in plants, it was first shown by M. Naudin, and is now well known to all hybridisers, that those which do not revert to type break out into an overflow of irregular variation, which supplies many of his most remarkable sports to the horticulturist, and many of his most puzzling difficulties to the systematic botanist. On the assumption that the mimicry in question is the result of hybridisation, we should therefore expect to find a marked degree of variation among the mimicking species. And so we do. Mr. Bates figures no less than fifteen varieties of *Leptalis Ithomiæ*, one of his mimics, which itself mimics seven different species (all very close to each other, however, and perhaps scarcely deserving the name of independent instances.) Mr. Trimen figures six varieties of *Papilio Merope*, which supplies four of his instances of mimicry, and Mr. Wallace's imitating Papilios were in like manner remarkable for their variations. It seems a fair inference that when the mimicking species are not variable they have been established before the second generation of hybrids, and where they are variable they have been established subsequent to the second generation, and have experienced the usual shock to stability occasioned by such repeated loosening of the fetters of specific identity.

Mr. Bates's list of mimics and mimicked species shows, too, that when a species is mimicked by one species or genus it is often mimicked by more, a fact which, applied to the idea of hybridisation, simply means that that species had a readiness to take to itself wives of more than one of the nations round about. Out of twenty-eight Danaoid species cited by him, which had been mimicked or had families from strange husbands, fourteen had families from one each, three from two each, and six from three each. It is only what we find in plants, that some are more open to hybridisation than others; or perhaps, analogous to our moral experience, that where scope is allowed to our own passions, license soon degenerates into libertinism.

Another feature, familiar to all hybridisers, occurs in these mimicries. Notwithstanding the statement of Wichura to the contrary, it is now perfectly well known that in attempting to obtain a cross between two species we often fail when we work with the male of one species and the female of the other, while we succeed when we reverse the process and take the male of the latter and the female of the former. In plants the cases where this capability of crossing in only one direction occurs are beyond number. Mr. Isaac Anderson Henry cites many of them in his late Presidential Address to the Botanical Society of Edinburgh, and in the paper which I have now the pleasure to lay before the Committee. The very same thing has occurred with the mimicries recorded by Mr. Bates. They are all on one side of the house. According to my view (indeed if hybridisation is once allowed to have been the motive power, it must be according to every one's view), the parents were the Danaids on the one side, and the cabbage whites (Pieridæ) on the other, for all the mimicked are Danaids with their special characters, viz., only four apparent legs, while all the mimickers, like the whites, have their special characters, six legs apparent. If they had been hybridised from both sides, we should have had some Danaids with the form and colour of the whites, as well as whites with the form and colour of Danaids; but we have not. The case which so often occurs in plants has obviously occurred here. The cross was taken only from one side. Which is it? I apprehend, from other examples, that it should be on the side of highest organisation—that is, that the male parent has been of the lower organisation, and the female parent (the actual bringer forth) of the higher. Now, which is the side of highest organisation in the Danaids and Pieridæ? Is it that of greatest strength? If it were so, it would then be the Danaids, for they are larger, finer, and more powerful than the more northern whites. But organisation is a higher test than mere strength. This, too, seems to be on the side of the Brazilian tribe. Mr. Bates so considers it, and his reason is that, the essential quality of butterflies being flight, the type which has most attention paid to its wings and least to its legs, must be highest of its order. Others think differently, and say that a type which has had two of its limbs (its anterior legs) almost atrophied, cannot be so perfect an animal as one which has them all in perfection. But I agree with Mr. Bates on this point (at all events in his conclusion). The greater number of legs cannot be any indication of higher organisation, or a centipede might dispute supremacy with ourselves, and push us from our stools. Multiplicity of sub-division or repetition of parts is acknowledged by all physiologists to be an indicatior on inferiority of organisation. The fewer limbs, that is the simpler the apparatus that a creature can do its work with, the higher the perfection of the machine. Therefore, doubtless, Brazilian Danaids are the higher type, and if (as I believe to be the case), in crosses of difficult accomplishment, the female is the higher parent, then the cross from which these mimics resulted was one by the males of the whites upon the females of the Danaids.

In what I have above said as to one-sided crossing, I have assumed that in plant-hybridisation the fact would be admitted; but as it is in contradiction to the statement of so eminent an authority as Wichura, I shall remove all doubt from the subject by quoting Mr. Anderson Henry. He says:—"I regret to differ from so great an authority as Wichura (who has maintained that 'the products which arise from reciprocal crossing in plants, unlike those which are formed among animals, are perfectly alike'), and must venture to demur to the doctrine in more decided terms than Mr. Berkeley does. I have had so many instances of hybrids taking sometimes to one side and sometimes to another, *but most frequently to that of the mother*, that to those who, like me, have tried their hand with many genera, it would be a matter of supererogation to give instances. I have had them by the score."

But the mixed product also corresponds with another fact observed in hybridisation. Mr. Henry informs me that in some of his crossings of plants he has only succeeded in altering the flowers, the foliage continuing persistently the same as that of one of the parents. He has not succeeded in distributing the union through all parts. That is exactly parallel to what we see in these mimicries. The number of legs and the nervation of the wings (in other words the more structural portions of the animal) remain special as in one parent, while the colour and form of the wings, &c., is taken from the other. In the butterflies it is the more structural parts (legs, nervures of wings, &c.) of the male parent which are observed in the offspring, while the form and general appearance only of the female parent is adopted. In plants it may be a question whether we should consider the flower or the foliage as the more structural parts—for my part I should take the flower as the more important, and therefore equivalent to the structure of the legs and wings; and the foliage and habit of the plant in Mr. Anderson Henry's case as equivalent to the colour and form of the wings and general appearance of the insect. Another phase of the mimicry, which I have no doubt will be found to have also its parallel in the hybridisation of plants, although I am not able to cite any instances exactly in point, is that in species which have dissimilar sexes, it sometimes extends to both sexes, the males being like the males and the females like the females, but in other instances is confined to the females. I believe that the reason why I have no case in point to cite in plants is that it can only be had in diœcious plants, and the hybridisation of diœcious plants has hitherto been scarcely at all attended to. Mr. Henry has some coming forward, but they have not yet flowered.

The last point to be noticed is one of some importance, as being the only one furnishing a shadow of objection to the explanation of the mimicries in question by hybridisation. It is that the nearest natural allies of both the mimickers and mimicked are *not* always to be found in the same district. This deserves the more attention, since it appeared so strong to Mr. Bates as to lead him to relinquish the idea of hybridisation as an explanation after it had crossed his mind. "The explanation," says he, "that the whole are the result of hybridisation from a few originally distinct species cannot at all apply in this case, because the distinct forms, whose intercrossing would be required to produce the hybrids, are confined to districts situated many hundred miles apart."

Before I proceed to show how simple the explanation of the absence of one of the parents is, I must beg to note in passing the admission that there are distinct forms whose intercrossing would produce the hybrids. That granted, I would remind the reader of what Mr. Bates has obviously overlooked, that we are dealing with a phenomenon probably of a very ancient date, and that one side of the parental stock may have disappeared in the course of time. I have elsewhere suggested, in regard to hybridisation as a possible originator of species, that it must be a necessary accession to such an event that the hybrids should have opportunity of isolation, such as might be obtained by thinly peopled districts where they might settle, spread, and establish themselves. Now, certainly, the Valley of the Amazons, the Malayan Archipelago, and many parts of the South of Africa (lands whence these mimetic analogies come) have at different periods all been at one time unoccupied land; for all of them have been raised from the bottom of the sea, and been peopled by the influx of the inhabitants of neighbouring lands. No one knows better than Mr. Bates that at one time Brazil was unconnected with New Granada or the Andes. The Danaids were then inhabitants of it, but not inhabitants of the countries about it; while the Pieridæ, or cabbage whites, were what I have elsewhere denominated a microtypal tribe from more temperate climes, and were present in the Andes and the mountain countries, as Columbia, connected with them. In the natural course of things, therefore, when the Valley of the Amazons was changed from the bottom of a sea to dry land, the Danaids would spread into it from Brazil, and the Pieridæ from the north and west, and meeting in an open, as yet, unpeopled country, hybridisation might take place under one of the few circumstances where I have thought it possible that it could retain its place and establish its products as species. The objection that frightened off Mr. Bates is, in reality, no objection at all to the hypothesis of the mimicry being due to hybridisation, that we are not always, or even that we should not at all be able to identify the probable parents of the mimickers as inhabitants of the same country as their supposed descendants. One of the parents we know to be present (the so-called mimicked), but there are excellent reasons why the other parent should not be present. It is of a northern type, suited for our temperate regions, but not adapted to the tropics except at a higher elevation and a cooler temperature than the damp, hot valley of the Amazons. Although, therefore, it might descend into that region, it is not only a natural but almost a necessary inference that it would not find it congenial or habitable, and although it might live long enough in it to found a dynasty of mimickers, it would soon die off from unsuitable conditions, while its hybrid offspring bred from the tropical Danaids might, from the black blood so imparted to them, find it sufficiently well suited for them.

There is yet another phenomenon connected with Mimicry, which possibly may also be connected with hybridisation, viz., the occurrence of what Mr. Wallace has called dimorphism in insects among the mimicking or mimicked species. We must not, however, confound this dimorphism with Darwin's dimorphism in plants. The two are totally different things, and, as it seems to me, have no relation or analogy to each other. In plants the dimorphism is always confined to the reproductive organs, in insects it has apparently nothing to do with them. Moreover, it seems to me that all the instances of so-called dimorphism in insects that have yet been recorded, are nothing but examples of variation, perhaps complicated by hybridisation. M. Reinhard, of Bautzen, has shown that this is the case with regard to Mr. Walsh's conclusions respecting the dimorphism of certain gall-flies, for he had found that the galls of various species appear to be so transitional between other forms, that they can only be known with certainty when the perfect insect appears. It appears to me to be also the case in all those instances where the dimorphism is confined to particular districts, as in the *Papilio Turnus* of North America, where all the females are yellow in the New England States and in New York, while in Illinois, and farther south, they are all black, and in the intermediate region, both black and yellow females occur in varying proportions. And the case is not open to any doubt, because in the intermediate district, both yellow and black insects have been bred from the same batch of eggs. Now, if the case had been that *both males and females* equally varied, and that in the south all were black and in the north all yellow, with intermediate gradations in the districts between, we scarcely suppose that any one would have thought of calling it a case of dimorphism. If they did, then all climatal variations (and their name is legion) would come under the same category. It is only dimorphism, because the change is limited to the female. But is this a good ground? Physiologists are unanimous in holding that neither the male nor the female is the species, but both; and if that be the case, in what does a variation in the female and not in the male differ from a variation in both but in degree? Most of Mr. Wallace's instances of dimorphism are of this character—the male being the same in a number of islands in each of which the female differs. All these I regard as mere instances of climatal variation, in which the variation shows itself only in that part of the species called the female. An occasional case of variation from some other cause, as from hybridism, may possibly come to complicate this phenomenon; but it appears to me to be sufficiently explained by variation, and the circumstance above mentioned is significant that where mimicry occurs in species having dissimilar sexes, it too is often confined to the female.

A. MURRAY

SCIENTIFIC SERIALS

Silliman's Journal, September 1870.—The opening article of this number is by Prof. E. Loomis, and is entitled "Comparison of the mean daily range of the Magnetic Declination, with the number of Auroras observed each year, and the extent of the black spots on the surface of the Sun." The author first discusses the observations of sun-spots, and points out some corrections that should be made in the numbers obtained by astronomers in the last century; he points out that the period is one of ten years, and is influenced by the heliocentric conjunctions of Jupiter and Saturn, but affected by the conjunctions of the Earth and Venus. By a series of tables and curves the coincidences of periods of the maximum number of sun-spots with the maxima of magnetic disturbance and auroral display are elucidated, from which it appears that the present year is a period of maximum.—In a letter to the editors, Mr. J. W. French proposes *a new period in chronology called the Precession Period*, of 25,782 years, being the time for the precession of the equinoxes. The author prefers this period, since it is founded solely on astronomical facts.—The third article is by F. W. Clarke, "On the atomic volumes of solid compounds," in which are discussed the relations of the volumes of analogous and similarly constituted bodies.—The next article, "Considerations on the apparent inequalities of long periods in the mean motion of the Moon," is by Simon Newcomb, and, after a long discussion on the observations on this subject, and the theories proposed to explain them, the author attributes the phenomenon to an irregularity in the rotation of the crust of the earth, caused by the motion of its fluid contents.—The following is a very interesting article by Dr. A. M. Mayer on "Researches in Electromagnetism." The author has devised a very accurate method of determining the relative values of electro-magnets to replace the one usually employed, which consists of measuring the deflection of a magnetic needle which is produced by the action of the electro-magnet. The author found that this process was liable to error in consequence of the difficulty of keeping the current absolutely constant, resulting in a continual motion of the needle. These difficulties were obviated in the following manner: A line eight feet long and divided into fractions of inches was drawn on a table, the latter being so placed that the line was at right angles to the magnetic meridian; a compass, with a needle nearly six inches long, was placed on this line, and a helix was fixed at each extremity of the line. These helices were traversed by the same current, a tangent galvanometer being placed in the circuit. In this way the needle was influenced by two magnets acting in opposite directions and excited by the same current, and if any deflection of the needle was observed, it must have been due to a difference of power of the magnets. If this occurred the needle might be brought to 0° by moving it from the stronger magnet. A series of experiments was made to determine the variation of the intensity of the force with a change of distance, by placing the needle opposite an electro-magnet and noting the deflection produced when the instruments were at different distances from one another: it was found that in the apparatus employed the intensity varied inversely as the 2·7404 power of the distance from the core. Dr. Mayer has determined the power of cores made of insulated and of non-insulated soft iron wires, and finds that the insulated core is slightly the weaker. He has also measured what thickness of tube is equal to a solid core of the same diameter, and has found that a solid cylinder ten inches long and 1·68 in diameter may be replaced by a tube of the same length and of a thickness of $\frac{1}{6}$ of the diameter. This relative size does not appear to be constant for cores of all dimensions. A longitudinal slit in the tube does not diminish its power; in fact, Dr. Mayer seems inclined to think that it facilitates its magnetisation. By placing a helix inside a soft iron tube a magnet is produced with poles the reverse of those of the coil, or of a bar placed within the helix; this supports Ampère's theory of magnetic currents. Numerous other experiments are detailed in this paper, and the author promises to employ his apparatus for the determination of the force of magnets of different sizes.—Mr. G. F. Barker contributes an abstract of the second series of Professor Meissner's researches on electrised oxygen, in which are detailed the author's experiments on the substance formed simultaneously with ozone which possesses the property of producing a white mist in contact with water. The original paper was published by the Göttingen Royal Society of Sciences.—Mr. A. E. Verrill describes a new species of Entozoön from the Hog. This is followed by some notes on the structure of the Crinoidea, Cystidea, and Blastoidea, by E. Billings, F.G.S.—The next article consists of contributions to chemistry from the laboratory of the Lawrence Scientific School, the first paper of which is by W. G. Leison, on the precipitation and determination of the metals of the magnesium group in the form of oxalates. For this purpose the solutions containing the metals are mixed with oxalic acid and alcohol, the precipitated oxalates washed, dried, and dissolved in hydrochloric or sulphuric acid, and the quantity of oxalic acid present estimated by means of a standard solution of potassic permanganate. A number of examples show the accuracy of the process.—J. H. Talbott describes the precipitation of zinc and manganese as sulphides, and the quantitative separation of tin and tungsten by fusing with potassic cyanide, by which the tin is reduced to the metallic state.—A new mode of treating gelatinous precipitates is suggested by T. M. Chatard, which consists in evaporating the liquid containing the precipitate to dryness, and stirring until the mass becomes a dry powder, which is then readily washed on a filter.—S. P. Sharples points out that antimonious sulphide precipitated by sulphuretted hydrogen in boiling solutions is granular and easily washed. Arsenious sulphide does not behave in a similar manner.—In the fifth section B. Godwin advises the repetition of quantitative analyses with the same quantity of material, the mean of the results being taken.—The next article is by Professor W. A. Morton on the corona seen in total eclipses. He calls the attention of astronomers to the importance of determining the positions of the more prominent portions of the corona with reference to the equator of the sun.—Dr. Finlay contributes observations on prehistoric archæology in Greece.—The remainder of the journal consists of extracts from other journals principally European.

THE *Geological Magazine* for December (No. 78) opens with a curious paper on Earthquakes, written about the year 1798 by Sir John Prestwich, an ancestor of the President of the Geological Society. This paper is interesting not only as showing the absurdities which passed as science not much more than seventy years ago, but also as giving a list, derived from old historical works, of the occurrence of earthquakes in England.—The most important article in the number is a continuation of Mr. H. Woodward's Contributions to the Knowledge of British Fossil Crustacea, containing descriptions of species of the curious genus *Cyclus* from the British Carboniferous rocks. Many of the species are described as new, and most of them are well figured. There is also an interesting article by Mr. George Maw, on Recent Changes of Level in the Coastline of the Mediterranean; and Mr. J. F. Walker describes and figures some *Brachiopoda*, from the Lower Greensand of Upware in Cambridgeshire, two of them as new species. Other papers are: "On the Age and Position of the Blue Clay in the West of England," by Miss C. Eyton; and "On the Dispersion of Granite Blocks over the Plain of Cumberland," by Mr. D. Mackintosh.

THE most important paper in the *American Naturalist* for November is one presented by Prof. Agassiz to the Troy meeting of the American Association for the Advancement of Science, "On the former existence of local glaciers in the White Mountains." He conclusively shows that whatever may have been the number of its higher peaks which at any given time during the glacial period rose above the great ice-sheets that then covered the country, this mountain range offered no obstacle to the southward movement and progress of the northern ice-fields. To the north of the White Mountains, as well as to the south, the northern drift consists of a paste more or less clayey or sandy, containing abraded fragments of a great variety of rocks, so impacted into the minutely comminuted materials as to indicate neither stratification, arrangement, nor sorting, determined by the form, size, or weight of these fragments. Large boulders and pebbles of all sizes are found in it throughout its thickness, and these coarser materials have evidently been ground together with the clay and sand under great pressure, beneath heavy masses of ice; for they have all the characteristic marks so unmistakeable now to those who are familiar with glacial action, scratches, grooves, furrows, &c. We have also articles "On the Habits and Migrations of some of the Marine Fishes of Massachusetts," by J. H. Blake; "What is the Washington Eagle?" and "On the Distribution of the Moose in New England," by J. A. Allen; "Notes on certain Inland Birds of New Jersey," by Dr. C. C. Abbott; and two reprints, "On the Cultivation of Alpine Flowers," and "Acclimatisation of Foreign Trees," both from the *Quarterly Journal of Science*, by Mr. A. W. Bennett. Further abstracts are also given of papers read at the recent meeting of the American Association for the Advancement of Science.

SOCIETIES AND ACADEMIES

LONDON

Royal Geographical Society, December 13.—Sir H. Bartle Frere, vice-president, in the chair. The following new fellows were elected:—Daniel David Dymes; Colonel T. G. Glover, R.E.; R. M. Gordon; Captain L. W. Longstaff, Edward Masterman, jun.; Don Pompeio Moneta (Chief Engineer Argentine Republic), Charles Pannel; Alfred Robinson; G. S. T. Scobell; and C. A. Winchester.—Lieutenant G. C. Musters, R.N., read a paper on his recent journey through Patagonia, from the Straits of Magellan to the frontier of the Argentine Republic. The author, having determined on this journey, landed at the Chilian penal settlement of Punta Arena, in the Straits, on the 15th April, 1869, and, having procured the goodwill of the governor, was permitted to accompany a party who were despatched across the country to recover some runaway convicts at the mouth of the River Santa Cruz. Here he made a friendly arrangement with Orkeke, the cacique of a tribe of Patagonians, to traverse the country with them as far as the Rio Negro. He studied their language and manners, and joined them in their hunting parties: the country abounding in game, chiefly guanaco, the three-toed ostrich, and the puma, or American lion, the latter of which was eaten as well as the rest. Frozen rivers and heavy snow-falls prevented their starting from Santa Cruz before the 12th of August. They travelled at first in a westerly direction, until reaching the foot of the Cordilleras, along which they marched for upwards of 700 miles to the upper waters of the Rio Negro, making a short, but important, detour across the River Limay, in the Cordillera due east of Valdovia. The author described the streams crossed throughout the route, the physical nature of the country, and its chief productions, and gave also long and most interesting details of the manners of the wild tribes, including an account of hostile encounters with other tribes. He stated that, when not excited, the Patagonians manifested a good-tempered and generous disposition, and that they were remarkable for their affection to their wives and children. The women have the whole charge of the tents, constructed of poles and guanaco skins, and the march of many months was an almost continuous chase after the game of the country. Every morning the chief gave his orders for the day in a set speech. The men, on starting, spread themselves over a wide space in the plains, in a crescent form, the more advanced of whom on each side, travelling fastest, as the whole cavalcade moves on, meet in front, and thus enclose the game in a circle; the women and children, with the baggage-horses, forming the base line of the crescent. In the earlier part of the journey four such marches were made in succession, averaging eight or ten miles each; then followed a rest of several days, in places where pasture was abundant. Lieutenant Musters was altogether more than a year with the tribe, who had come to look upon him as one of themselves. In May 1870 he crossed the country again from west to east, and on the 21st of that month arrived at the Argentine settlement of Patagonia, near the mouth of the Rio Negro. The climate of the country, in which he reached north of 40° S. lat., he describes as cold and ungenial; snow fell at midsummer, and the greatest heat experienced in the warmer months was only 65°.

Geological Society, December 7.—Mr. Joseph Prestwich, F.R.S., president, in the chair.—1. "On Fossils from Cradock and elsewhere in South Africa." By Dr. George Grey. From the Karoo-beds, Dicynodont fossils and the jaw of a reptile (*Estheriæ*), and some coal and coal-plants (*Lepidodendron*, *Sigillaria*, &c.), were the chief specimens noticed by the author. Some *Stigmariæ* from the Old Coal of Lower Albany, and gravel and miscellaneous minerals from the diamond fields, formed part of the collection. 2. "On some Points in South African Geology," Part II. By Mr. G. W. Stow. This paper commenced with a detailed account of the forest zones, coal, and other strata of the Karoo formation, as seen in sections in the Winterberg and Stormberg. The author particularly pointed out the position of the fern-beds at Dordrecht, of the Reptilian remains found on the Upper Zwartkei, and of the coal on the Klass Smits River. He next referred to the climatal changes of South Africa, as indicated by its geology and fossils, particularly the Karoo-beds, the *Enon* conglomerate, the *Trigonia*-beds, the several Post Tertiary shell-beds, and especially the present surface conditions, which he regarded as due to ice-action, as evidence of which he adduces *roches montonnées*, moraines, basins, and striæ, both north and south of the Stormberg, in British Kaffraria, and even in Lower Albany. He concluded with remarks on the probable succession of periods, and on the former existence of a great southern continent. Prof. Ramsay expressed a hope that the author at some future time would discuss the numerous subjects of which he treated at greater length and under separate heads. He was not surprised at the finding of Carboniferous plants in the Dicynodont beds which appeared to be of Triassic age, inasmuch as the same was the case to some extent in our own later beds of Oolitic date. He agreed in the view of the probability of a vast continent having formerly existed in the southern part of the world, and considered that the denudation of Southern Africa had been so great, that it was no wonder the boundaries of the old freshwater lakes were no longer easy to find. It was also by no means surprising to him that a recurrence of glacial phenomena should be found in Southern Africa, as it had been in Europe. He did not, however, think it necessary to call in the action of ice for the excavation of valleys such as some of those described, as rain and running water appeared to him sufficiently powerful for the purpose. At the same time he would not deny the possibility of ice having been the agent in these cases. Mr. R. Tate had seen evidence of similar effects being produced by aqueous force to those resulting from glacial action, and cited instances of moraine-like deposits having been formed by running streams in Central and Southern America. Mr. H. Woodward suggested that it would be desirable to wait for further particulars of the sections before asuming the actual association of the *Lepidodendron* and other plants. He added that the *Stigmaria* lately said to have been obtained from the Kimmeridge clay, had really come originally from Newcastle. Prof. T. Rupert Jones remarked that Mr. Stow, like other South African geologists, had had ample experience of the effects of violent rain. With regard to the mixture of Palæozoic plants, such as the *Lepidodendron*, &c., sent by Dr. Grey with *Palæozamia* and *Pecopteris*, he thought it somewhat analogous to the mixture of palæozoic and mesozoic fossils in Australia. 3. "On the Geology of Natal, in South Africa." By Mr. C. L. Griesbach. The author commenced by describing the physical geography of Natal, and then indicated the characters and distribution of the rocks which occur in that country. He stated that the granitic and gneissic rocks do not form the most prominent elevations, but they appear chiefly in the lower parts of the river-valleys, and sometimes in small hills. Mica-schists and slates are found associated with the granites. The great plateaux consist of an undisturbed sandstone, which the author identifies with the Table-mountain sandstone, and which lies horizontally upon the granites and old slates. The tops of many of the table-mountains in Natal are crowned by beds of dark basaltic greenstone. The Karoo formation, which lies in part upon the Table-mountain sandstone, consists of a vast series of sandstones and shales, some of the latter containing beds of coal. The author agreed with Mr. Tate in regarding these beds as of Triassic age. At the base of the Karoo formation the author described a boulder-bed, which he was inclined to identify with the rock described by Mr. Bain as "Claystone porphyry," and through this greenstone has forced its way. On and near the coast of the southern part of Natal, some sandy marls and sandstones belonging to the Cretaceous series were said to occur; the author gave lists of fossils obtained from these deposits, which he identified with the Trichinopoly series of India. Several of the fossils were described as new species. The author considered that the evidence adduced indicated that, after the development of the Table-mountain sandstone, Africa and India formed parts of one continuous continent, afterwards covered by the Cretaceous sea. The area now covered by the Indian Ocean was the basin of a large series of lakes; and this condition persisted through a long period of tranquillity, lasting through the Triassic to the Upper Jurassic age. The greater part of this continent was then depressed and covered by the shallow Cretaceous sea. The economic mineral products of Natal were mentioned by the author, who referred to the occurrence of graphite, coal, gold, and copper. Prof. T. Rupert Jones commented on the importance of the paper as throwing so complete a light on the geology of Natal, and proving the geological sequence to be similar there to that in other parts of Southern Africa. He remarked that the author had done special service by the great increase of information furnished by him regarding the Cretaceous rocks of Natal, and their equivalence to those of India. He also pointed out that Mr. Griesbach had proved that the Karoo formation was continuous to the other side of the great dividing range, and formed the floor of the Orange and Waal Valleys, and that as Mr. Stow had indicated glacial action on the south side of the Orange Valley, it was quite possible that the gravels containing the diamonds were of local origin, as Dr. Grey had suggested. 4. "On the Diamond-Districts of the Cape of Good Hope." By Mr. G. Gilfillan. Mr. Gilfillan described his going through Colesberg to Hopetown, and thence across theOrange River to Backhouse; and then, after crossing the Vaal, up its right bank as far as Lekatlong. He noticed such diamonds as he saw or heard of, and described the locality as being thickly coated with sand, diamond-bearing gravel, and tufa, hard blue shales occurring here and there in protruding hills. Prof. Tennant stated that he had lately seen as many as 500 diamonds from the South African fields in the possession of one person, some weighing as much as 50 carats. He had seen another fragment of a stone which must have originally been at least as large as the Koh-i-noor.

Ethnological Society, December 13.—Professor Huxley, president, in the chair. Mr. E. Rowley Morris was announced as a new member. Mr. Grove, Q.C., exhibited a dozen skulls from a large collection in the crypt of Rothwell Church, in Northamptonshire; and Professor Busk, F.R.S., made some remarks upon their anatomical peculiarities. The skulls are, on an average, smaller than those of the existing race, and many exhibit an extreme lowness of forehead. Some of them are referable to Prof. Huxley's "river-bed" type. The discussion on these remarks was sustained by the President, Mr. Galton, and Mr. Evans.—Sir John Lubbock, Bart., read a paper "On Stone Implements from Africa," in which he described some implements of the spear-head type from the Cape of Good Hope, and some small polished celts brought by Mr. Reed from near Accra on the Gold Coast. He also exhibited a small, but exquisitely-worked flint implement found in Syria. Mr. A. W. Franks, Mr. W. Blackmore, Mr. E. B. Tylor, Mr. J. W. Flower, Mr. Hyde Clarke, and Mr. E. B. Pusey, took part in the discussion on Sir John Lubbock's paper.—A collection of stone implements was exhibited by Dr. Hooker, C.B.—Some notes from Mr. Edgar Layard were read relative to some stone spear-heads, hammers, flakes, cores, &c., from South Africa.—A second report "On the Present Condition of the Prehistoric Antiquities of Dartmoor," was presented to the Society by Mr. C. Spence Bate, F.R.S. The author described in detail several stone circles, bee-hive huts, and avenues on the south of Dartmoor, especially in the neighbourhood of the Avon and the Erme. On Trowlsworthy Tor is a curious circular enclosure, with two entrances so constructed as to admit only a single man at a time, which the author regards as a specimen of early military engineering.

Linnean Society, December 15.—Mr. Bentham, president, in the chair. Dr. J. Lindsay Stewart was elected a member of the council in the room of the late Dr. Anderson.—"On Sabadilla (*Asagræa officinalis* Lindl.) from Caracas," by A. Ernst. A large quantity of this drug is exported from Caracas and Venezuela, amounting to from 3,000 to 3,500 quintals annually, almost the whole being sent to Hamburg. The plant is a very common one by the roadsides in Caracas, but the greatest part of the drug (obtained from the seeds of the plant) comes from the hilly regions in the south, where it grows at an elevation of from 3,500 to 4,000 feet. It was originally discovered in the Mexican Andes, and is not known elsewhere. Although not mentioned by Humboldt, it is, however, apparently indigenous in Venezuela, growing in places where it is most unlikely to have been planted, and having been known long before the seeds were first exported by German druggists. The Caracasian plant differs slightly, but hardly specifically, from the typical form of Mexico. The bulbs contain numerous raphides of oxalate of lime.—"On the Pitcher-plant of California (*Darlingtonia*)," by W. Robinson, F.L.S. The Californian Pitcher-plants grow in the Sierra Nevada, at an altitude of 5,000 feet above the sea, in small sloping bogs along with *Sphagnum* and other true bog-plants. At a distance the pitchers have the appearance of jargonelle pears, holding their larger ends uppermost, at a distance of from 10 in. to 24 in. above the ground. This resulted from the pitchers being quite turned over at the top so as to form a full rounded dome, and the uppermost half of the pitcher being of a decided ripe pear-yellow. They are all twisted spirally, especially in their upper portion. Each pitcher had at the bottom a layer of from two to five inches of the remains of insects closely packed into it; from those of minute beetles to large feathery moths. What it is that attracts the insects is by no means clear. Pass a sharp knife through a lot of brown pitchers withering round an old plant, and the stumps resemble a number of tubes, densely packed with the remains of insects. Within the pitcher the surface is smooth for a little way down; then isolated hairs appear; and soon the chamber becomes densely lined with needle-like hairs, all pointing down, so decidedly indeed, that they almost lie against the surface from which they spring. These hairs are very slender, transparent, and about a quarter of an inch long, but have a needle-like rigidity, and are perfectly colourless. The poor flies, moths, ladybirds, &c., seem to travel down these conveniently arranged stubbles, but none seem to turn back. The pitcher, which may be a couple of inches wider at the top, narrows very gradually, and at its base is about a line in diameter. Here, and for some little distance above this point, the vegetable needles, of course, all converge, and the unhappy fly goes on till he finds his head against the thick firm bottom of the cell, and his rear against myriads of bayonets; and here he dies. Very small creatures fill up the narrow base, and above them larger ones densely pack themselves to death in the hope of fighting their way out. When held with the top upwards; sometimes a reddish juice, with an exceedingly offensive odour, drops from them. The plant is closely allied to the *Sarracenia*, and would no doubt be easily grown in this country.—"On Carnivorous and Insectivorus Plants," by Mrs. Barber (Cape Town).

Norwich

Norfolk and Norwich Naturalists' Society, Nov. 29.—The Rev. J. Bates delivered a lecture on "Sun-spots," illustrated by numerous diagrams. After explaining the various and changing appearances presented by sun-spots and faculæ, and the electrical disturbances in the earth's atmosphere which accompanies them, Mr. Bates briefly reviewed the theories which have been advanced from time to time to account for these remarkable phenomena, and concluded by explaining the wonderful light spectrum analysis has thrown, not only upon the composition of the sun itself, but even upon the atmosphere by which it is surrounded, and the stupendous commotions by which it is constantly agitated.—Mr. Barrett read a paper "On certain coast insects found near Brandon." In June last Mr. Barrett captured at Brandon several species of moths, whose habitat was essentially coast sand-hills, and which he believes were not suspected to exist at any considerable distance from the sea. The nearest sea-coast to this locality would be upwards of twenty miles distant, and delicate insects such as the tiny *Gelechia desertella* and the weakly constructed *Anerastia lotella* would not voluntarily undertake so long a flight, and it is impossible, considering their frailness and the nature of the intervening country, to admit of their having been "blown across" to their present locality. Mr. Barrett therefore submits that as this tract of country was undoubtedly a range of coast sand late in the post-glacial period, when the great valley of the Fens was still submerged. These little insects are probably the descendants of an ancient race which has survived the physical changes of ages, and that possibly their very weakness has preserved them in a locality now far removed from what is considered their natural habitat. The specimens exhibited were identical in appearance with duplicates obtained from the coast, and the only difference observed in their habits was their earlier appearance, about a fortnight before the coast specimens, doubtless due to the warmer and more sheltered locality. Mr. Barrett's paper was followed by a discussion, in which some curious facts bearing upon his theory were elicited, amongst others the nesting of a coast species of bird (*Charadrius hiaticula*), in the same tract of country, these birds having, as it were, two distinct places of existence, one portion nesting on the sea beach far away, the other frequenting the ancient coast line which may have formed their breeding place countless ages ago. Seals found living in the Caspian Sea, in which the waters are only one-fifth the saltness of the open sea, are identical with those found in the North Sea and probably in the Mediterranean. Another species found in Lake Baikal, which is fresh water, is also found on the American coast. These, it was contended, were descendants of the oceanic seals, left by the subsidence of the water after the glacial period.—The President read some notes on the birds of New Zealand, from a letter recently received by him from his brother at New Plymouth, Taranaki. Speaking of the disappearance of small birds, which has been attributed to injuries inflected upon them by the bees on which they are supposed to have fed, and which have increased enormously, his correspondent altogether discountenanced the idea, attributing their disappearance to the disturbances of war, bush fires, and perhaps climatal changes. He adds: "I suspect that terrestrial commotions have altered our climate; since our last great earthquake, our winds have altered in their intensity, frequency, and direction. Report states that there has been a great disruption of Antarctic ice, which to me explains the frequency of penguins, mostly young, being among the rocks here, and the capture of two sorts of seals, the common seal and seal lion, both young, quite close to the town, though they have never been seen here since this was a settlement. The natives say they were common enough before the Europeans came, and they still call certain rocks on the beach by the names of the sort of seal that once frequented them. Some of the birds, however, appear to be returning to their former haunts.

Glasgow

Geological Society, December 1.—Mr. John Young, vice-president, in the chair. *Bituminous Striped Sandstone.*—The chairman exhibited a block of carboniferous sandstone from Gilmorehill quarry, about nine inches in thickness, showing in that space thirty-two well-defined alternate white and dark-brown stripes, which gave the specimen a beautifully stratified appearance. Mr. Young stated that the brown stripes were due to the particles of sand having become mixed with bituminous matter previous to their deposition. *Carboniferous Fossils.*—Mr. Thomas Naismyth exhibited several drawers of fish remains, principally from the coal-fields around Glasgow, upon which Mr. Young offered a few remarks illustrative of their generic characters and their range in the carboniferous strata. The collection contained a number of fine large teeth of *Rhizodus Hibberti*, from the ironstone pits at Possil; jaws, scales, and teeth of *Megalichthys Hibberti* and *Megalichthys rugosus*, besides a number of fin-spines and other fragments of fishes, from the Airdrie coal-field. Among the specimens were also to be noticed a few fragments of reptilian remains, consisting of portions of crania, vertebræ, &c., which had been found near Airdrie, and at Quarter, near Hamilton. *Oil Shale.*—Mr. D. C. Glen, C.E., laid before the meeting several slabs of oil shale from near Collingwood, on Lake Huron, Canada; and also some samples of the petroleum distilled from it. The slabs were from the Silurian formation, which is of great extent in North America, and remarkable for the regular succession of its strata. When examined, these blocks of shale were found to be stratified horizontally with layers of Trilobites, Entomostraca, and other marine organisms. It was from the prodigious abundance of these crustaceans over this track of ancient sea-bottom that the shales now referred to had received their bituminous ingredients.

Perth

Perthshire Society of Natural Science, December 2.—Dr. Buchanan White, president, in the chair. Mr. W. Herd exhibited two specimens (♂ and ♀) of *Dasypolia templi*, recently found by him near Perth. Intimation was given that the first number of the *Scottish Naturalist*, a quarterly magazine of natural history, published under the auspices of the Society, and supported by most of the leading Scottish naturalists, would appear early in January.—Mr. J. Sadler, F.R.P.S.E. (of Edinburgh), read a paper "On the Geographical Distribution of Plants in Perthshire." He traced the range of various characteristic plants from the sea-level up to the summit of Ben Lawers, the highest mountain in the county, and pointed out the distribution of the rarer species in other parts of Britain. In reference to *Saxifraga cernua*, which in Britain has only been found on the summit of Ben Lawers, Mr. Sadler said that in the opinion of some botanists the Ben Lawers plant was only an Alpine form of *Saxifraga granulata*, but in his opinion it was a good species. The paper was illustrated by an interesting series of diagrams, formed of dried specimens of the plants. One of these diagrams showed the altitude attained by the various plants found on Ben Lawers from its base to its summit.—The President read a paper upon "A Naturalist's Work in Winter." He divided his subject into two divisions, "Out-door Work" and "In-door Work," and pointed out what could be and should be done in the various branches of natural history during the winter months.

PHILADELPHIA

Natural Sciences Society, July 5.—The president, Dr. Ruschenberger, in the chair. Mr. Meehan exhibited some specimens of *Rumex obtusifolius*, a naturalised dock from Europe. He said that so far as he could ascertain from European specimens, and the descriptions of Babington, Bromfield, and other English botanists, the plant was there hermaphrodite; but here, as correctly stated by Dr. Asa Gray, it was monœciously polygamous. He thought the fact that plants hermaphrodite in one country becoming unisexual in another, was worthy of more attention by those engaged in the study of the laws of sex than had been given to it. This *Rumex* did not stand alone; *R. crispus* and *R. patienta* exhibited the same thing. *Fragaria* was another instance well known to horticulturists, although the fact scientifically had not received due weight. The average tendency of the strawberry in Europe was to hermaphrodism—here to produce pistillate forms. He also called attention to the fact that in these American specimens unisexuality was in proportion to axial vigour. This law he had already explained in times past to the Academy, and new instances were scarcely necessary. Here, however, the moderately weak plant had more hermaphrodite flowers than the strong one; and in both classes of specimens the number of male flowers gradually increased with the weakening of the axis, until the ends of the raceme were almost wholly of male flowers. The first flowers on the strong verticels were usually wholly pistillate. Prof. Leidy remarked that the interesting communication of Mr. Meehan had recalled to his mind a result of his experience, which he thought would accord with that of others, viz., that species viewed as common to both Europe and America frequently exhibit slight peculiarities, which are distinctive of those of the two countries. It is what might be inferred even if we admit the evolution of existing species from a common remote ancestry. A wide separation, with a considerable lapse of time and a modification of circumstances, are sufficient to account for the slight and acquired differences. Even where differences are not observed in form and structure, they may exist in the habit of the species. Thus the common wolf of Europe and America, viewed by many naturalists as of the same species, differs strikingly in character in the two countries. In the former it is a more fearless animal, not hesitating to attack man; in the latter, it is said never to attack man. At an early period observers saw, or thought they saw, many of the same species of plants and animals indigenous to America that occur in Europe, and hence the common nam s of European species were applied to those of America. Gradually the list of species common to the two countries was much reduced, and now is comparatively small.

August 2.—Mr. Vaux, Vice-president, in the chair. Mr. Thomas Meehan called attention to the arrangements of some plants for preventing fertilisation through any other than insect agency, as discovered by Darwin. The *Salvia* family of plants had the most elaborate arrangements for insect agency, but it had been objected to Darwin's theory that insects made no use of them. Bees bore holes through the tube from the outside for the honey, and do not enter by the mouth of the flower, as they ought. In the same way, in the *Petunia*, bees bore for honey from the outside. He had discovered that in these cases, where day insects failed to make use of these apparatuses, fertilisation was carried on by night moths, so that the objections to Darwinism were removed. He also referred to the common sweet chestnut, as bearing two classes of male flowers, only one of which probably aided in fertilisation. The first class appeared ten days before the other, and are those which give whiteness to the trees. They appear in the axils of the weak shoots. The female flowers appear on the apices of strong shoots, according to his theory of the laws of sex. The second class of male flowers appears at the ends of the vigorous shoots bearing the female flowers. Whatever affects the vigour of the tree interferes with the production of female but not of male flowers, and this was the reason why some seasons had short crops.

BOOKS RECEIVED

ENGLISH.—Text-books of Science; Inorganic Chemistry: W. A. Miller, M.D. (Longmans and Co.).—Method and Medicine, an Essay: B. W. Foster (Churchill).—Science, Creeds, and Scripture, and the Mystery of God: (Blackwood and Sons).—A Laboratory Text-book of Practical Chemistry: W. G. Valentin (Churchill).

FOREIGN.—(Through Williams and Norgate)—Theoretische Astronomie: Dr. W. Klinkerfues.—Handbuch der allgemeinen Himmelsbeschreibung: H. J. Klein.

PAMPHLETS RECEIVED

The Education and Status of Civil Engineers (published by the Institution).—Spectrum Analysis: a Lecture by W. Huggins.—Spectrum Analysis: a Lecture by Prof. Roscoe.—Coral and Coral-reefs: a Lecture by Prof. Huxley.—Proceedings of the Annual Meeting of the Natural History Society of Montreal.—Proceedings of the Cleveland Institution of Engineers.—Science Education abroad: a Lecture by Principal Dawson.—Description of New Fossil Shells of the Upper Amazon: T. A. Conrad.—On the Heat developed in the combination of Acids and Bases: Dr. Thomas Andrews.—New Remedies: Dr. M'Elroy.—Provisional Catalogue of Transactions of Societies, Periodicals, and Memoirs in the Radcliffe Library.—Essay on the Comparative Efficiency of Spectroscopic Prisms of different Angles: E. C. Pickering.—Abstracts relating to the Preservation of Food: W. H. Archer.—Experiments on the Transpiration of Watery Fluid by Leaves: W. R. McNab, M.D.—Applicazione della teoria Darwiniana ai fiori ed agli insetti visitatori dei fiori: F. Delpino.

DIARY

THURSDAY, DECEMBER 22.

ROYAL, at 8.30.—Actinometrical Observations made at Dehra Doon and Mussoorie, in India: Lieut. Hennessey.—On the Constitution of the Solid Crust of the Earth: Archdeacon Pratt, F.R.S.—On the Extension of the Coalfields of England beneath the Newer Formations, and the Successive Physical Changes whereby they have been reduced to their present Dimensions: E. Hull, F.R.S.

FRIDAY, DECEMBER 23.

QUEKETT MICROSCOPICAL SOCIETY, at 8.

TUESDAY, DECEMBER 27.

ROYAL INSTITUTION, at 3.—Burning and Unburning: Prof. Odling (juvenile lectures).

THURSDAY, DECEMBER 29, 1870

SCIENCE AT SCHOOL BOARDS

THE country may, we think, be congratulated on the election of School Boards in London and the provinces. Although from our point of view it may be deplored that so few men of Science, or persons having any pretension to understand what Science means, have been elected, it must be felt that the beginning of a great work has taken place in this country, the end of which no one can at present foretell. The nation, for the first time in its history, has taken the subject of education into its hands. The Education Act will be open to alteration and revision in the Houses of Parliament, and from step to step we may hope to see at last a department of Government representing the wishes of the people, dealing alike with the education given in our universities and our ragged schools. The great aim of the country must be to give to every child born in the kingdom the best education adapted to secure its happiness and usefulness in this world. There is no doubt that this will be the feeling that will prompt members of the various School Boards to carry out the powers which have been given under the Education Act.

We exceedingly regret that the various Boards have been elected rather upon a religious ground than upon the general principle of what is desirable to be taught in the schools. As we read the Act, there will be little opportunity left to the Board to increase or alter the conditions of "religious teaching" in any of the schools. It would have been better, perhaps, to have excluded all religious teaching from the primary schools, on the grounds, first that the feeling of respect and even awe which ought to attend the teaching of the Bible, is likely to be diminished by making it a common reading and task-book in schools; and secondly, that the clergy of the Established Church and of the various denominations, who are amply paid for their religious ministrations, ought especially to undertake religious teaching, and conduct it under circumstances that would render it most efficient and useful in the moral training of a child. There is also a third objection, and that is that the rate ought not to take the money of one set of people for the purpose of teaching the religion of another. There are certain moral obligations underlying all the higher religious creeds, to which no parent could possibly object, which ought to be taught and insisted on everywhere in universities as well as primary schools.

With regard to the other subjects to be taught in the schools, we would call attention to the danger there is that any extension of the means of education should lead to an imitation of the system now in existence. That system consists almost entirely of giving lessons out of books and teaching children words independent of the facts they represent. The present Chancellor of the Exchequer has well said, "I think it is more important for a man to know where his liver is seated and what its functions are, than to know it is called *jecur* in Latin and ἧπαρ in Greek." Of course there is no chance of Latin and Greek being introduced into our primary schools, although if they are such a precious means of developing the mind as they are assumed to be, there seems to be no reason why they should not. But the substitute for these branches of human acquirement is found in our lower schools in the shape of reading poetry, history, geography, and the like. If the sentiment of the Chancellor of the Exchequer exists in the new School Boards, the time seems to have come when some effort may be made to give up a certain amount of time in all schools to the teaching the facts of the external world. This is what is usually called scientific training, and has been almost universally regarded in our systems of education as something that may be dispensed with. But Science is after all but a systematic arrangement of observed facts by which the laborious investigations of the few may be made the possession of the many.

It may be urged in favour of this teaching that it educates (draws out) portions of the mind which cannot be cultivated by means of words and figures or moral lessons. A boy may be able to read all languages and master all problems in mathematics, and be a moral paragon, and yet commit some stupid blunder, from ignorance of some obvious chemical, physical, or vital law, that may cost him his life, or, what is more important still, may lead to the death of others. Our whole national history is full of terrible instances of punishment for breaking obvious and easily understood natural laws.

That Natural Science can be taught in schools there is no doubt. It has been introduced in a limited way into our great schools, as Harrow, Rugby, and Eton; and, so far as it has gone, it has not only not been attended with any diminution of acquirements of other branches of knowledge, but rather the contrary. In some of the national schools in Ireland, Science has been introduced, and we can bear testimony to the amount of useful information acquired by a class of boys in chemistry at the National School in Sligo.

The most difficult question for the School Boards to determine will be how to begin. In nine cases out of ten they have no men of Science to direct them. There is one comfort in London, that the Board will have a host in Professor Huxley, who, if they will listen to him, is undoubtedly capable of giving good advice. He will be ably backed by Miss Garrett, who, with her medical education, will be fully able to appreciate both the subjects and methods of any attempt to teach Science in our schools. Mr. Lucraft, the working man's candidate, has also advocated the teaching of Natural Science in schools. If the other candidates said anything on this subject, the reports of their speeches have not yet reached us. Still we may hope and we would especially recommend to the reading of all members of School Boards a "Report of a Committee appointed by the British Association on Scientific Education in Schools." It is a parliamentary paper, published in March 1868. We do not think this paper had the attention paid to it demanded by its intrinsic importance; and we are glad to recommend it, as especially adapted for the reading of members of School Boards and of all interested in education.

Without having any cut and dry system to offer to the public, we would advise that some attempt be made to teach some quantum of Natural Science somehow. The present masters will probably be utterly ignorant of any branch of Science, but there are plenty of students of Science who would undertake at first to instruct, perhaps in several schools. They should be instructed to teach children to observe facts, and lead them gradually from simple facts to the more obvious and easily understood laws of Science. Such classes are formed in Germany, in what are called *Real Schule*, and the system has been introduced into England under the name of Object lessons. Such teaching might be preparatory to taking up any one branch of Science, such as Chemistry, Experimental Physics, Botany, or the elements of Human Physiology.

We are glad to find that this subject has again been taken up by the British Association for the Advancement of Science. A few days ago a deputation of this Association waited on the Vice-President of the Council for the purpose of presenting a memorial on scientific teaching in elementary schools. Their reasons for urging this subject, they say, are three : "Firstly," the memorial says, "we conceive such teaching to be one of the best instruments of education in the sense of intellectual discipline, and in many respects better calculated to awaken intellectual activity than other studies ; secondly, we think that a knowledge of the elements of Natural Science has a high value as information; and thirdly, we are of opinion that scientific training and teaching in the elementary schools will afford the best possible preparation for that technical education of the working classes, which has become indispensably necessary to the industrial progress of the country." The subjects they propose to be taught are elementary Physical Geography, elementary Physics and Chemistry, elementary Botany, and elementary Human Physiology. They think that by such an education the children of "the poor and necessitous" might be prepared to take advantage of the scholarships and exhibitions which are now only open to the children of the well-to-do classes of society.

E. LANKESTER

THE LEARNED SOCIETIES AND THE PRESENT CONDITION OF SCIENCE AND LEARNING

THE appointment of the Royal Commission on the present condition of Science will naturally turn the attention of many minds to the subject, and its discussion will certainly elicit many suggestions and schemes for the better culture of knowledge. The question is so large, so important, and so difficult, that the freest possible discussion will be necessary for its satisfactory solution.

At present we wish to direct attention to the question as to how we may obtain from the Learned Societies of the United Kingdom the greatest possible aid in the improvement of natural knowledge. The number of these societies is now large. Some of the provincial societies can claim an honourable place even when compared with the associations which are not confined to any one locality in their choice of members. Members of the Literary and Philosophical Society of Manchester, it should be remembered, were the first who were favoured with Dalton's Atomic Theory. Of what we may call the national societies, the number is increasing yearly, greatly to the detriment of real progress. Membership in these societies is coveted because it is supposed to indicate the possession of certain acquirements, it being thought, not unnaturally, that the members have won their spurs as investigators and interpreters of Science. Nor can we conceive of any better tests than those at present applied to candidates. Examinations are clearly impossible in this case, even if one were fully confident of the certainty of that method for detecting ability. It is evident that, on the whole, the regulations now enforced have been successful in their object, and that membership of a British Learned Society is generally not only a coveted distinction, but one deservedly prizeable.

Year by year these societies gather up the result of patient investigations, of long and careful research. Recording new facts, illustrating old truths, dissecting error, they pursue a course of steady consistent usefulness. Every one who has had to work up some special topic, must have a feeling of gratitude for the aid he has received from their publications. The societies are doing a good share of honest work, and doing it well. Their ranks include the most distinguished and the most ardent investigators in each branch of learning. Still we need not attempt to disguise the fact that they do not contribute so largely to the advancement of knowledge as it is desirable they should do. They have forgotten, or never known, that unity gives strength. They have neglected the great fact, daily becoming more apparent, of the unity of knowledge.

"The divisions which we establish between the Sciences are, though not arbitrary, essentially artificial. The subject of our researches is one : we divide it for our convenience, in order to deal the more easily with its difficulties. But it sometimes happens—and especially with the most important doctrines of each Science—that we need what we cannot obtain under the present isolation of the Sciences,—a combination of several special points of view ; and for want of this, very important problems wait for their solution much longer than they otherwise need do. To go back into the past for an example : Descartes's grand conception with regard to analytical geometry is a discovery which has changed the whole aspect of mathematical science, and yielded the germ of all future progress ; and it issued from the union of two Sciences which had always before been separately regarded and pursued." (Comte.)

Science suffers not only from the causes indicated in the preceding extract, but also from the dispersion of material in different receptacles, all of which are not accessible to the student. If the number of existing learned bodies be taken into consideration, and also their conflicting claims, it will be obvious that none except rich men can possess all the aid which they can give to the investigator. A paper upon the characteristics of one of our English dialects might appropriately be read before the Royal Society, the Society of Antiquaries, the Philological Society, the Archæological Institute, the Archæological Association, the Royal Society of Literature, the Ethnological Society, the Anthropological Society, and a score or more of the provincial societies. We find a valuable monograph on the Lancashire dialect in the Proceedings of the Philological Society, and another in the Transactions of the Literary and Philosophical of Liverpool, but for information on the eastern variety of that dialect, we must go to the Historic Society of Lancashire and Cheshire. The Cheshire glossary must be sought in the Archæologia, the Cumbrian in the Royal Society of Literature.

The same confusion may be predicated of almost every subject that can be taken up for inquiry. And, in spite of the multiplicity of societies, there is greatly needed throughout the length and breadth of the land a network of intelligent observers. We propose, as a remedy, that the present chaotic want of system be superseded by a National Institute for the Advancement of Knowledge. Such an institute might readily be obtained by the amalgamation of the present societies into one homogenous body. Whatever of interest and of value British savants might bring before it would be welcome and appropriate, and would be accessible to the student of the "knowledge which is one." In its organisation, the first labour would be the classification into sections. Whilst, on the one hand, there would not be three or four sections to perform the same work, on the other hand the entire domain of human knowledge could be fairly occupied, which is not the case at present, and the divisions marked with much greater accuracy than is now possible. The members residing in each district would form a local section, hold their meetings at regular intervals, and be a committee charged to watch over and promote the interests of Science and Learning in their particular neighbourhood.

In this brief and necessarily imperfect outline, much is omitted. Advantages not here indicated would result from the creation of a National Institute for the Advancement of Knowledge, but it is hoped that enough has been said to prove the desirability of such a foundation, having for object the attainment (in the words of Bacon) of "the knowledge of causes and secret motions of things; and the enlarging of the bounds of humane empire to the effecting of all things possible."

WILLIAM E. A. AXON

PROF. BALFOUR STEWART'S ELEMENTARY PHYSICS

Lessons on Elementary Physics. By Balfour Stewart, LL.D., F.R.S. (London: Macmillan and Co.)

THIS is a bold experiment, and decidedly deserves to be a successful one. Nearly all our elementary works, even on mere *departments* of Physics, are extremely bad, especially the so-called "original" ones; and those which have been translated from the French are little suited to the genius of this country—however excellent they may be in France—while they are usually spoiled by inaccurate translation, or by clumsy and injudicious addition of a mere cobbling or patching kind.

The reasons are not far to seek. It is very rarely that we find in this country a genuine scientific man who can, like Faraday or Herschel, make himself easily intelligible even on difficult subjects to an ordinary reader; still more rarely that we find such a man to have paid such special attention to the merest elements of his subjects as to thoroughly understand them himself, which ought to be regarded as an absolutely indispensable preliminary to his teaching them to others. Take for instance the question of the measurement of temperature in conjunction with the second law of thermodynamics, that very second law itself, or its connection with the equality of radiating and absorbing powers. Take even a simpler matter, the notion of a standard pound as a definite quantity of matter, not as something which shall be attracted by the earth with a certain force. Try all the elementary works in succession, and, if you are not driven mad by their inconsistencies and want of definiteness, endeavour to give in a clear, intelligible form the result of your studies on any such questions as those just mentioned. If you had no notion to begin with, you will have none, or worse than none, at the end; and, even if you began with thorough knowledge, you would probably end helplessly confused, doubting the simplest and most obvious truths. But this is the way we do things at home; and hard, indeed, must be our British heads, which, after they have managed our "*As in præsenti*," &c. &c., can plunge into this further chaos, and rise, as they often do, refreshed and invigorated by the struggle. A Frenchman, perhaps even a German, would perish in the attempt. But for them the path is made comparatively easy.

Nothing seems plainer than this—that he who has been ill-taught in the elements of his subject, however he may advance in knowledge (which is always a man's *own* work, whoever be his teacher), can hardly hope to understand these elements well enough to teach them to others. They have become to him a hateful thing, so he pushes on and avoids them as much as possible. Hence, that we may have really elementary works of a strictly scientific kind, we must have, not merely a genuine scientific man to write them, but one whose elementary instruction was good, or one whose strength has enabled him to get over its imperfections. These qualifications are certainly united in Dr. Stewart, for he had the late Principal Forbes for his teacher, and he is himself a man of quite exceptional powers, both in experiment and in reasoning.

It is scarcely possible to form a judgment as to the probable success of the present work. It is so utterly unlike anything to which we have been accustomed, that we can only say we never saw such a work, in English, at all events. Nothing so perfectly elementary, and yet throughout so intensely suggestive, have we ever met with. Even while reading the introductory chapters, we have several times laid down the book to follow trains of reasoning suggested by a single happy phrase that showed us something with which we had considered ourselves familiar, from a perfectly novel and interesting point of view. This, of course, will not strike the beginner, neither will it impede his progress; for it is not learned and abstruse disquisition or discussion, it is simply the clear vision of the writer.

Dr. Stewart does us much more than justice in the Preface, for he exaggerates the importance of a few suggestions of ours, made only with the view of keeping him to *his own plan*, which we consider to be an admirable one. The grand modern ideas of Potential and Kinetic Energy cannot be too soon presented to the student; he ought to be familiarised with them as soon as he commences the study of Physics. In fact, we believe that before many centuries have passed, perhaps before fifty years have elapsed, the word Force will have become as much a nuisance and an impediment to the beginner in Physics as the phrase Centrifugal Force is already.

However this may be, the work before us is an excellent one, and will certainly (*if there be teachers found sufficiently* *instructed to recognise its merits, and sufficiently humble and enterprising to stoop to learn anew, and by a better method, the elements of their science*), take its place at the head of elementary treatises on its subject. It is by no means faultless: no first edition on so new a plan could quite avoid confusion; there is excess of detail on many points, too little on others, and the language, though generally correct throughout, is sometimes almost mystical. This is not a reproach—quite the reverse—for it is mainly in these passages that we feel the strength of the author, and we are unfortunately not speaking from the beginner's point of view. He has evidently thought deeply, and the result is in all cases well worthy of careful study, especially for those who think themselves thoroughly masters, if but of the merest elements. No one can read the work without feeling that he has still something to learn, even in the most prosaic parts of the science. Dr. Stewart does not, as it were, follow the ordinary laws of war; he abjures pipe-clay and red tape, and he has a method of his own which we cannot but think is calculated to do a real service to the beginner. Even methods in mathematics cannot be stereotyped; Euclid is about to be laid on the shelf; and it is not at all unlikely that in a few years the so-called Cartesian x, y, z, will disappear, to make way for Hamilton and his vectors. Thus it is, and shall be, with the so-called *statical* proofs of the Parallelogram of Forces, we shall get back to Newton's methods as nearly as modern nomenclature will permit; and so likewise in other parts of physics. The reign of *inartificiality* and *simplicity* must soon be inaugurated, and this work will greatly tend to hasten its advent.

It would be improper to finish without finding some additional fault, especially after all we have said in praise of the work, and even Dr. Stewart's recent accident (from the effects of which we are delighted to hear he is steadily recovering) must not influence us.

The printing is excellent; but some of the woodcuts (the balance, p. 59, and the strained beam, p. 71, for instance) are not merely execrable, but, what is far worse, misleading. No mention is made of the Peltier effect at a thermoelectric junction, nor is Sir W. Thomson's so-called "specific heat of electricity" alluded to, though both might easily have been introduced without increasing by more than a page or so the bulk of the volume. These are matters of such fundamental importance, and are capable of such easy description, that they certainly ought to have been given. There are other points of a similar kind, but it is not necessary to mention them.

Dr. Stewart very fully treats of the grand question of the equality of Radiation and Absorption, the question which first brought him prominently before the scientific world; but he has done it with such an excess of modesty that his own genuine claims might be endangered, were there not happily other works in which his services to this important branch of science are fully recognised.

It is peculiarly sad that Prof. Stewart should have been temporarily disabled just when he was getting into working order his Physical Laboratory in Manchester: no one is better fitted for such work than he is; let us hope that he may soon be in a position to resume the direction of it, and to teach beginners by means of his excellent Manual.

P. G. TAIT

OUR BOOK SHELF

The Academy. Vol. I. (London: Williams and Norgate. 1870.)

WE congratulate our twin brother (or sister?) the *Academy*, on the appearance of its first volume. The journal had at its starting a clear *raison d'être*, to respond "to a widely felt and constantly expressed dissatisfaction with the existing organs of literary and scientific criticism." The wide field embraced in the programme has rendered the editor's task anything but an easy one. Of the literary department it does not come within our province to speak; the scientific portion, we can fairly say, has been honestly and ably executed. This department consists of two sections—original reviews, and scientific notes. The former, in accordance with the practice of the rest of the paper, are all signed. The desirability of signed articles is one that has been much debated. Whatever may be its relative advantages or disadvantages in literature or politics, we are convinced that in science the former greatly outweigh the latter. In reading a criticism on a scientific work, it is before all things necessary that we should know that the critic has a right, from his own knowledge of the subject, to speak with authority. The signatures to the scientific articles which will be found in this volume are themselves sufficient guarantee that the subject is discussed from a standpoint from which something is to be gained by the reader. The scientific notes consist of paragraphs under the various heads of chemistry, physics, geology, zoology, botany, physiology, &c., epitomising the most important discoveries or researches of the month. Though the subjects are rather unequally treated, the notes have evidently been drawn up with great care by competent men, and the whole gives a very fair *résumé* of the more important advances in each department of science. If we might mention one section that appears to us to have been particularly well done, it is that of physiology. A list of the new books of the month, English and foreign, is also given, and the titles of the more important scientific magazine articles, with occasional abstracts of them. We notice with pleasure the conscientious manner in which the editor invariably acknowledges the source of his information, a practice we could wish to see more generally carried out by his brothers of the craft. Other literary journals have been content hitherto to supply their readers with their modicum of science either second-hand and very much out of date, or with a disregard to accuracy which has rendered it perfectly valueless. The *Academy* is doing good service in bringing scientific subjects before educated readers who have no special scientific bias, in a style that is likely to interest them in it, and in a manner that may be relied on as sound and accurate, and calculated to increase the knowledge in which they are, as a rule, so lamentably deficient.

Die Praxis der Naturgeschichte. Zweiter Theil: Dermoplastik und Museologie, oder das Modelliren der Thiere und das Aufstellen und Erhalten von Naturaliensammlungen. Unter Mitwirkung von Präparator Bauer, Prof. Dr. G. Jäger, Stadtdirektions Arzt Dr. Steudel, und der Thier- und Landschafts-Maler, Paul Meyerheim und Friedrich Specht; von Philipp Leopold Martin. 8vo, pp. 240, six plates. (Weimar: B. F. Voigt. London: Williams and Norgate 1870.)

FEW tasks are more distressing to a right-minded naturalist than the inspection of the ordinary mounted specimens of animals in most museums in this country and elsewhere. More hideous spectacles than usually meet one's eyes when visiting these establishments it is impossible for man to form, or mind to imagine. Some little advance, it is true, has been made of late years, upon what was formerly the prevailing type of a "stuffed beast." But no real reform can take place until the curators of museums have come to recognise the great truth, that, unless such objects are properly mounted, it is worse than useless to exhibit them to the public at all. They should be taken down and stowed away in drawers, or preserved in any other way that may be convenient for scientific study. Left in their glass cases, they are much more likely to repel than to attract the ordinary observer, for whose benefit the exhibition is intended.

Under such circumstances we cannot receive otherwise than with pleasure a treatise prepared with the view of teaching the true principles of the art of taxidermy and their proper application. The Royal Cabinet of Natural History at Stuttgart is well known to those who have visited it as one of the few institutions of this kind where real care and skill are exhibited in the mounting of the specimens, and no one can be more fitted than its energetic "*preparateur*" to give instructions upon a subject of which he has shown such perfect knowledge. Herr Martin has, moreover, obtained the assistance of several individuals who are fully qualified to assist him in his task, which appears to have somewhat of a comprehensive scope. In a former part of the present work, Herr Martin has treated of the various methods of collecting animals of all sorts in the field, and of preserving them for scientific purposes. The fact of a third edition of this former part having been already called for shows that the work has been appreciated by those or whose instruction it is designed. In the present section of his volume, Mr. Martin and his fellow-workers treat more especially of the processes to be performed in the museum itself, such as the modelling in plaster of beasts large and small, the formation of preparations of the internal organs, the making of skeletons, and the mounting of microscopical objects. Full instructions are likewise given upon every point connected with the practical working of a public museum, not only as regard the objects themselves, and the best mode of exhibiting them, but also in relation to the wants and requirements of the visitors that resort to such institutions.

P. L. S.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Mimicry versus Hybridity

BEFORE attempting to combat the old theory under which Mr. Murray has taken refuge, in opposition to the theory propounded by Mr. Bates, I must first make a few remarks upon the different forms of mimicry to which the Lepidoptera are subject.

Mimicry may be divided into two heads, viz.:—the mimicry of one lepidopterous insect by another, and the mimicry of the vegetable kingdom, and of backgrounds generally, by Lepidoptera. As Mr. Murray doubtless refers to only the first of these heads when he speaks of hybridisation, I need not trouble the reader with any remarks respecting the second. Mimicry, then, between butterflies and moths, may again be divided into three sections: that which modifies both sexes, that which chiefly modifies the females, and, lastly, that which chiefly modifies the males;* these variations of modification are all easily explained by the theory of protective assimilation variously adapted to the economy of the different modified species; but it can in no way be explained by the theory of modification by hybridity. Mr. Murray speaks of hybridisation as if it were a thing recognised by lepidopterists, and of no uncommon occurrence, whereas it has, so far as I know, only occurred in the Heterocerous Lepidoptera, and only between species of the same genus; there is, indeed, a case on record of a skipper butterfly and a burnet moth being taken *in coitu*, but no reasonable being could expect that any issue would result from such an union; again, I maintain that if it were even possible for hybridity to occur between different sub-orders, families, or even genera of Lepidoptera (which, by the way, is as likely as hybridity between a vulture and a dove or a horse and a rabbit), the offspring would inevitably be modified in structure just as much as hybrids between distinct races or species of vertebrates are; they would moreover, if fertile, certainly revert to one or other of the parent stocks, which, however we do not find to be the case; if the fertilisation of flowers and butterflies were the same, hybrids might be as common in the one case as the other, and the results attained might be more nearly alike; but as butterflies are not fertilised through the transmission of pollen by external agencies, and as they seem to have a decided preference for mates belonging to their own peculiar species, hybridisation must needs be a thing almost unknown amongst them. Lastly, I need scarcely say that the fact of birds hunting by sight and not by smell only does not in any way destroy the argument respecting the favoured and non-favoured species of Lepidoptera; the same thing may be said of lizards, frogs, dragon-flies, and spiders, which all of them persecute the order, and which all avoid not those insects only which have a peculiar odour, but those which, like the *Danainæ*, *Heliconinæ*, *Acræinæ*, and others, have an acrid taste resulting from an offensive liquid which they exude from the body. I have been more fortunate than Mr. Scudder, inasmuch as I have frequently seen birds catch and devour the unprotected species upon the wing, whilst I have received abundant evidence both from scientific and non-scientific collectors respecting the perfect immunity which the *Danainæ*, &c., enjoy from all kinds of persecution, whilst their less fortunate brethren come to an untimely end.*

British Museum ARTHUR G. BUTLER

* An interesting illustration of this type of mimicry exists between the genera *Belenois* and *Mylothris*, the males of the African group of *Mylothris* being identical in colour with males of the genus *Belenois* (sub-family Peirinæ).

* The Hon. Mr. Justice Newton, who assiduously collected and took notes upon the Lepidoptera of Bombay, informed me that the *Charaxes Psaphon* of Westwood was continually persecuted by the bulbul, so that he rarely captured a specimen of this species which had not a piece snipped out of the hind wings; he offered one to a bulbul which he had in a cage, and it was greedily devoured, whilst it was only by repeated persecution that he succeeded in inducing the bird to touch a *Danais*, which he offered to it.

I AM rather surprised that Mr. Andrew Murray should have advanced his theory of mimicry being due to hybridisation, without adducing one solitary fact to prove that hybridisation between distinct *families* of insects ever occurs, or that, if it do occur, the offspring are fertile *inter se*. Mimicry is most frequent between very distinct *families* or higher groups, and often between different *orders* of insects. We may fairly consider that the "natural orders" of plants, as being the next well-marked groups above genera, are about equivalent to the *families* of insects, so that the analogy furnished by hybridisation among plants, on which alone Mr. Murray's theory is founded, wholly breaks down, unless he can show (which he has not done) that such hybridisation occurs between species of different "natural orders," or of well-marked groups higher than genera. It would be mere waste of time to discuss the details of a theory whose fundamental assumption is not only quite unsupported by fact, but is diametrically opposed to the almost, if not quite, universal fact that hybrids do not occur between species of different families or higher groups.

Mr. Scudder's letter contains some interesting and suggestive facts, and opens up a new field of investigation as to the immunity of certain species, in their egg or larva state, from the attacks of hymenopterous and dipterous parasites. It is, I believe, now stated for the first time, that the peculiar secretions which render the Danaidæ distasteful to birds not only extend to their larva and egg state, but act as a safeguard from the attacks of parasites. The objection that it would have been more advantageous for the larva than for the imago of the *Limenitis misippus* to mimic the *Danais archippus*, appears to me to have no weight. We do not know, for instance, if such mimicry would be any defence against parasites who may be guided by smell rather than sight; and from the frequent limitation of certain odours and secretions to whole genera or families, the variations necessary to produce them may be of rare occurrence.

The fact that *Limenitis misippus* and *L. ursula* are about equally plentiful is not at all remarkable, since there are species of all degrees of rarity in every extensive group; but in this case it happens that both insects are mimickers, *Limenitis ursula* resembling the common N. American *Papilio philenor*, especially on the under side, which is exposed when the insects are at rest. This case of mimicry is not so perfect or so striking as the other, but that it is one is pretty certain, and there are several other instances in various parts of the world in which *Papilios* of certain groups are the objects of mimicry. Although Mr. Scudder has never seen a bird capture a butterfly, others have been more fortunate, and that they are thus captured very largely in the tropics is certain. It is not improbable, from the rarity of mimicry in the temperate zone, that the few cases which exist may have been produced under the more favourable climatal and organic conditions of the semi-tropical epochs anterior to the glacial period. ALFRED R. WALLACE

The Difficulties of Natural Selection

THE papers read by me before the Entomological Society "On the Relation between the Colour and the Edibility of Lepidoptera and their Larvæ" having been noticed and commented upon by Mr. A. W. Bennett and others in NATURE, I have deemed it desirable to offer a few remarks on the subject.

The object I had in making the experiments was to ascertain whether there could be proved to exist any relation between the colours of larvæ and their edibility.

The disciples of Mr. Darwin argued that the brilliant colours of so many male birds arose from sexual selection, and that the equally striking colours of flowers were but guides to insects, to enable them to distinguish, at some distance, the flowers from the leaves, and thus insure fertilisation by the interchange of pollen. Such reasons, however, were quite valueless to account for the bright colours of the asexual larvæ of many Lepidoptera, several species of which are banded and striped with blue, yellow, and red; colours which instead of concealing them by harmonising with the leaves on which they feed, are often in complete contrast with them.

Now Mr. Wallace had a theory that these gaily coloured larvæ were uneatable by birds, and that their gay colours were protective, because if they were indistinguishable from eatable species, they would be seized by birds, and though rejected afterwards, would be so much injured that the probability of their becoming imagines would be very remote, even if they were not at once killed.

This I found to be the case; in my experiments extending over many years, and most carefully made with several species of birds, I have not met with one instance in which a strikingly-coloured larva was eaten. In most cases they were not even regarded when thrown into the aviary, although I had several birds always on the watch for the eatable species, with which I constantly fed them; while these latter were seized immediately they were seen.

The larva of the *Cucullia verbasci* is conspicuously coloured blue and yellow, and feeds without any attempt at concealment on several species of Verbascum. I placed the plants in the aviary, and fed the Cuculliæ upon them until every leaf was devoured, and the caterpillars gnawed holes in the stem; but not one was in the slightest degree injured, yet at the same time other larvæ were greedily eaten.

On the other hand, I found that all larvæ were eagerly eaten which have soft smooth bodies and dull colours, while the hairy larvæ are rejected entirely.

These eatable species are protected in various ways; some are nocturnal in their habits, descending to the ground during the day; some feeding on the under sides of the leaves; others arrange their bodies in a line with the shoots of the plants and look like a streak of the bark; some are of precisely the colour of the leaves, or even of the corolla of the plant on which they feed; others roll themselves up in leaves, the larvæ of the *Geometridæ* are often exactly like twigs, with the terminal and side buds imitated.

This latter resemblance is so complete that, after being thirty years an entomologist, I was deceived myself, and took out my pruning scissors to cut from a plum-tree a spur which I thought I had overlooked. This turned out to be a larva of a Geometer two inches long. I showed it to several members of my family, and defined a space of four inches in which it was to be seen; but none of them could see that it was a caterpillar. Surely this was a case of protective mimicry.

All the eatable larvæ agree in not moving when there appears the least danger, and very rarely moving at all during the day.

Even if there were no cases of protective mimicry in the larval states of Lepidoptera, I do not think that would be any argument against the existence of such in the perfect state. It appears to me rather that as so few specimens become imagines in proportion to the eggs produced, the more need is there that these few should survive.

I cannot, therefore, agree with Dr. Scudder in thinking that mimicry has been supposed to exist where it is least wanted, viz., in the perfect state of Lepidoptera. Nor can I coincide with Mr. Bennett that it is a matter of indifference to the supporters of the theory of Natural Selection whether twig-like caterpillars are eaten by birds or not. My point is that they are often so like twigs that they are passed over as such by insectivorous birds, and that the closer the resemblance the better their chance of escape.

I believe myself that Mr. Darwin's theory will survive, and even be benefited by, the criticisms of its opponents; but what I do dread is the injury it may receive from the false arguments of some of its illogical supporters.

Lest I may unwittingly place myself in the latter category, I will bring my remarks to a close. J. JENNER WEIR

Butterflies and Birds

A CORRESPONDENT in NATURE, Dec. 22, states that after fifteen years' experience in butterfly hunting, he has never seen one in a bird's bill. I was not aware the circumstance was unusual, for I have frequently seen the common sparrow chase and capture such butterflies as *V. urticæ* and *P. rapæ*. It is quite a hare and greyhound affair, the butterfly often eluding for some time the swift pounces of its pursuer, so that the hunt is a long one. T. G. B.

St. John's College, Cambridge

Ceratodus Forsteri

SIR PHILIP GREY EGERTON presents his compliments to the Editor, and would esteem it a favour if he would insert the following paragraphs, from two letters recently received from Professor Agassiz, in an early number of NATURE. It will be gratifying to all men of science to know that the distinguished Professor has so far recovered from his late severe illness as to be able again to interest himself in scientific pursuits.

Oulton Park, Tarporley

"Cambridge, November 9

"I am slowly recovering, and find myself gradually returning to the ways of active life. As I wake anew to feel an interest in scientific pursuits, there is nothing for which I have a greater longing than the fossil fishes. If I could leave my house I would fly to you to resume the examination of your and Lord Enniskillen's collections. The recent discovery of Krefft has added fuel to the fire, and I feel the most intense desire to revise the facts bearing upon the relations of the Ganoids and Selachians in general, and more particularly those of the Cœlocanthi, to which, from the examination of the skeleton sent me by Krefft, I find his *Ceratodus Forsteri* belongs. It will no doubt turn out that the Dipterini are close relations. In this connection I am reminded of what you once wrote to me of the teeth of Ctenodus. Will you now have the kindness to give me all the particulars? I am having sections of the teeth of *Ceratodus Forsteri* and some of the fossil species made for comparison. I have little doubt already that this genus will turn out to be one of the most curious *synthetic* types (I call them) in the animal kingdom, exhibiting characters of Placoids (Selachians) in the teeth, Ganoids in the scales, their embryonic characters in the preservation of a dorsal chord, instead of distinct bony vertebræ, and finally hollow bones as in birds."

"Cambridge, Dec. 8

"I take it some of your naturalists will crow over what they will be pleased to call my stupendous mistake in referring the teeth of Ceratodus to the Selachians, when the fish proves to have large imbricated scales; and yet I never was more pleased than when I learned the fact, for it settles beyond dispute the existence in nature of types, to which I have long ago called attention, under the name of *synthetic types* (see my Essay on Classification), but of which naturalists have thus far taken little or no notice. When I described the teeth of Ceratodus as those of a distinct genus among the Cestracionts, I was led to do so by appearances which secured for this association the assent of all naturalists. As long as the fossil teeth only were known, nobody questioned the relationship. Owen himself, in his 'Odontography,' mentions the teeth of Ceratodus and their structure, and has not a shadow of a doubt that I am right in placing that genus near Cestracion; and now comes the discovery that Ctenodus, a genus also referred to the Cestracionts, is based upon the dental plate of a bony fish, closely allied to the one recently discovered by Krefft, and referred by him to the genus Ceratodus. Is not all this the most palpable evidence that there exist in nature types which combine structural features that are entirely separate in other types? and it is to such types I have applied the name of synthetic types."

Lumiere Cendree

IT may perhaps be of some interest to you to know that the phenomena of "Lumière cendrée" was distinctly seen in Surrey on the evening of the 25th inst., between 4 and 5 P.M. With the aid of an opera-glass, I saw clearly the whole of the dark portion of the moon's disc; and some friends who were with me at the time were able to see it with the naked eye.

H. G. S. SMITH

Trinity College, Cambridge, Dec. 27

Measurement of Mass

WITH reference to the very favourable notice in your last number of my edition of Deschanel's "Traité de Physique," will you allow me to remark that my reason for rewriting the section on *mass* (§ 42) was that Deschanel, in accordance with what has been till recent years an almost universal custom, employs a variable unit of force, and, as depending upon this, a variable unit of mass, so that the number denoting the mass of one and the same body is diminished as the body is carried from the equator to the poles, and would increase up to infinity if the body fell to the centre of the earth.

The reviewer says, "the conception of *mass* is always a difficult one for a beginner." This is doubtless true when the conception is hampered with the inconsistencies arising from this vicious system of measurement; but I do not think the conception of a *pound* or *gramme* of matter presents much difficulty, and these are the units in which, according to the best modern usage, I have indicated that mass is to be expressed.

As regards the coefficient of absorption of ammonia, the reviewer is right. A mistake was committed in extracting the number from a table, of which, if I may judge by his initials, the reviewer is the author. In future, I would entreat him to make his tables more easy of reference.

J. D. EVERETT

Belfast, December 26

Hailstones

IN NATURE of the 15th there is an account of hailstones of a form deviating considerably from the spherical. Hailstones are frozen raindrops, and a rain-drop falling through a vacuum would of necessity be spherical, but in falling through the air it must tend to assume the form of least resistance, whatever that may be. I was told many years ago of hailstones which had been picked up and found to be of the form of Minié bullets. I do not vouch for the truth of this, but I think it likely; the Minié bullet was, I believe, the nearest approach to the form of least resistance that the inventor was able to arrive at.

JOSEPH JOHN MURPHY

Old Forge, Dunmurry, Co. Antrim, Dec. 20

Darlingtonia Californica

MR. ROBINSON's suggestion, reported at page 159, as to the cultivation of this plant in England, has been anticipated by Messrs. Veitch and Sons, who have grown the plant for a considerable time in their houses at Chelsea.

In London, as in California, this curious plant possesses the same irresistible attraction to insects, and as I have repeatedly examined living plants at Chelsea, perhaps the following notes taken in connection with those printed in your last number may have some interest.

This so-called "pitcher plant," when fully grown, resembles in shape the upraised head and body of an excited cobra, with hood expanded and prepared for a spring; the head is at right angles with the hollow vertical body, and apparently presents no opening by which an insect could enter; under the place where the lower jaw would be, hang two large reddish appendages like the "wattles" of a fowl. At Chelsea this plant possesses such an extraordinary attraction for flies (principally blue-bottles), that the hollow "pitchers" are generally full of their dead bodies; what this attraction is I am unable to say, as the plant is scentless.

Last year I had a Darlingtonia before me for some three or four hours, whilst sketching it, and I then observed that the blow-flies made straight for it immediately they entered the room. Insects alight on the red "wattles" and then fly upwards into the (previously unseen) red-lipped entrance to the tube; owing to the sudden twist in the neck of the pitcher, they are at once compelled to descend the hollow body, and, as far as I have observed, they never return alive. They keep up a buzzing noise for half an hour or so, and then apparently die.

The old "pitchers" are generally full of dead flies, &c., and the lowermost insects, in rotting, cause the "pitchers" to decay and split, the flies within being then displayed. These dead flies often drop out through the fissures and become grouped round the bottom of the plant.

WORTHINGTON G. SMITH

Aurora Arcs in the East

I AM inclined to agree with Dr. Burder as to the invisibility of Auroras by daylight, yet I can confidently assure him that I have many times seen the arch "almost due east," that is when the extremities point N.N.W. and S.S.E. When such a phenomenon occurred in Newfoundland, some of the old weather-wise settlers would tell me to expect falling weather (snow or rain) on the following day, as the Northern Lights were in the south. But I am sorry to say that I did not note how often the Aurora appeared as above, but I *did* note that snow fell on *seventy-eight* consecutive days in the autumn of 1867 and commencement of the winter of 1868.

HENRY REEKS

The Milky Way

IN the number of NATURE for November 17, Mr. John Jeremiah states that "Heol y Gwynt" is the only proper Welsh name for the Milky Way. Such is far from being the case. I am acquainted with no less than *nine* other names, equally proper for that luminous appearance, such as *y llwybr llaethog*, *y ffordd laeth*, *llwybr y gwynt*, *galaeth*, *eirianrod*, *crygeidwen*, *caer Gwydion*, *llwybr Olwen*, and *llwybr y mab afradlawn*. Of these names, *y llwybr llaethog* and *y ffordd laeth* answer precisely to Milky Way; *llwybr y gwynt* (common enough in Carmarthenshire) is synonymous with *heol y gwynt*; *galaeth* (from *llaeth*, milk) corresponds with galaxy; *eirianrod* signifies a bright circle; and *crygeidwen* a white cluster. To *caer Gwydion* (the mural enclosure of Gwydion) belongs a tale, which may be compared with the stories of classical antiquity on the same subject. Gwydion is a noted character in early Welsh romance, in which he figures as an astronomer and an enchanter. He was the son of Don, king of Llychlyn or Scandinavia, and is said to have lived in the fourth century. According to the Welsh poets, he travelled through the heavens in search of a lady, who had eloped with Gronwy Befr, and left a track behind him, which has ever since been called *Caer Gwydion*. When he found the faithless lady he changed her into an owl. His scientific acquirements are often mentioned in Welsh mythology, and frequent allusions are made to him as an enchanter by the early bards. He is said to have been instructed in magical arts by Math ab Mathonwy, and in the Mabinogi, or tale which bears the name of the latter, his achievements are detailed at length. According to some of the Welsh records he was buried at Morfa Dinlle, on the seashore near Carnarvon.

Gwydion is not the only one of the family of Don whose name is associated with astronomy. Don himself gave his name to the constellation of Cassiopeia, which is called in Welsh *Llys Don*, the Court of Don; and *Caer Arianrod*, the Corona Borealis or Northern Crown, is so called after his daughter Arianrod.

Llwybr Olwen (the path or course of Olwen) refers to another distinguished character in Welsh mythology. Olwen was the daughter of Ysbyddaden Bencawr, a prince of the Northern Britons, who lived in the sixth century. Her extreme beauty was proverbial, and her charms are frequently alluded to by the ancient bards. It is stated of her that four white trefoils sprang up wherever she trod, and from this circumstance she was called *Olwen*, or white track. She was sought in marriage by Cilhwch, prince of Clyddon, and his adventures in order to obtain her form the subject of the Mabinogi of Cilhwch and Olwen, which will be found printed, with an English translation, in Lady Charlotte Guest's "Mabinogion," ii. 197,249

What connection the other name, *llwybr y mab afradlawn* (the path or course of the prodigal son), may have with the

Milky Way, is not obvious, as I am not aware of the existence of any fable bearing on the point.

D. SILVAN EVANS

IN reply to Mr. Reeks, I was quite correct in stating that the wind would blow in the course of the Milky Way; and to be sure of it, I have communicated with my friend at Llangadock, who has repeated what I have previously stated. He also tells me that on Sunday night (the 11th inst.) he looked out and found the "wind blowing from the east, and the Milky Way was to be seen coming from the north-east." He still thinks it possible to predict the weather by this kind of observation. However, apart from this, the Welsh word is sufficient to prove the correctness of my former letter, which means the "Road of the Wind."

Dec. 13 JOHN JEREMIAH

Meteoric Shower

I OBSERVED a most beautiful star-shower on the night of the 5th inst., at about a quarter to nine o'clock. It crossed the "tail" of Ursa Major in a direction almost easterly, and slanting towards the earth at about an angle of 30°. At first the phenomenon resembled the flight of a flock of wild geese, but after a little the nearer stars inclined towards the earth more than those farthest away, so that in all I could see about thirty stars. I write to you as the period of recorded star-showers mentioned in Prof. Ansted's Physical Geography, is from Dec. 6th to 13th, and I observed this star-shower on the 5th December.

The Commons, Killybegs, Dec. 14 JOHN C. WARD

Hereditary Deformities

THE articles upon this subject in NATURE, Sept. 8, Oct. 20, and Nov. 3, remind me of what I learned fifteen years ago while visiting tribes of Sioux Indians, assembled to the number of 5,000, near the mouth of the Yellow Medicine River, in Minnesota. The Indians were collected at this point for the purpose of receiving their annuities from the U.S. Government, and were accompanied by their families. It is customary for the squaws of their tribes to have tattooed upon the prominences of their cheek-bones small discs, of from one-eighth to one-fourth of an inch in diameter. I was informed by a physician, who has passed much of his time with these tribes, that sometimes a child was born with these marks. This was confirmed by the U S. Government Indian Agent. I had no means of verifying these statements; they were believed by my informants, who were gentlemen of veracity.

CHAS. M. WETHERILL

Lehigh Un versity, Nov. 19

Right-handedness

CANON KINGSLEY is a close observer of nature, and if his generalisation be correct in the following instance, it would seem that the tendency to develop the right arm to the comparative neglect of the left is not confined to man. In describing the call-crabs of Montserrat, he says that one of the claw-arms, generally the left, is dwindled to a mere nothing, and is not seen, while the other is disproportionately large. I am well aware that the claws of lobsters are seldom equal in size, but have had no opportunity of ascertaining whether it is the right or the left claw which is superior, nor whether there is any rule in the matter.

C. J. R.

Sun Stroke

IN the *Revue des deux Mondes* for the 15th August (page 854), there is a remark which, though somewhat exaggerated, is of very great value and practical significance. The writer says, "The phenomenon known as 'Sunstroke' is due to the action of light, and not, as is generally believed, to the elevation of temperature." An exception has to be made in cases where the sun playing, especially on the back of the head and neck, produces unmistakeable sunstroke. Every surgeon practising in the East also meets instances of "solar apoplexy," which present themselves as often as not during the night, but only in the excessively hot weather. However, I know from personal experience that it is quite possible to lay oneself up completely with intense headache, constant nausea, cold extremities, &c., by exposing the eyes only to the glare of the sun, the head and neck being completely sheltered by a helmet and *puggree*, and the body being at rest in a carriage. Further, I have found it possible, when accidentally obliged to expose myself, to avoid all inconvenience by merely wearing deeply-smoked glasses, my head being guarded only by an ordinary felt hat. But this is an experiment not to be tried rashly. The conclusion obviously is that whenever there is an intense glare, whether attended by intense heat or not, the first condition to fulfil is to shelter the eyes. As the retina is in truth an expansion of the brain, the brain is more accessible to external influences through the eyes than through any other avenue.

R. A. JAMIESON

Shanghai, Oct. 24

GLYCERINE EXTRACTS OF PEPSIN AND OTHER FERMENTS

A SHORT time ago Von Wittich published in *Pflüger's Archiv* some interesting results of an attempt to isolate, by means of concentrated glycerine, pepsin and other so-called ferments found in animal and vegetable bodies.

The mucous membrane of a pig's stomach, washed and freed as much as possible from water, was finely minced and bruised, and then covered with pure glycerine. After standing twenty-four hours, a few drops of the glycerine, diluted with acidulated water, digested fibrin with remarkable rapidity. After pouring off the whole of the glycerine, a second, third, and even fourth glycerine extract could be made, all manifesting strong peptic powers. On treating, after filtration, these glycerine extracts with a large excess of alcohol, a slight precipitate was obtained, which, separated by filtration and re-dissolved in acidulated water, though giving only the faintest proteid reaction, was strongly peptic.

In a similar manner salivary gland and pancreas gave up to glycerine an amylolytic or starch-converting ferment, almost entirely free from proteids, and a "laden" pancreas also gave up a ferment capable of digesting fibrin in an alkaline medium. Barley (*not germinated*) gave up to glycerine a non-proteid diastase; and almonds a ferment capable of acting on amygdalin.

I have repeated many of Von Wittich's experiments with almost entirely similar results. We certainly have in glycerine a new means of working out the intricate problems of these so-called ferments. The glycerine extracts, for the most part at least, seem to remain unchanged for a very long period, so that a stock of ferment can always be kept in store. On the other hand, tissues may, by repeated extraction with glycerine, be exhausted of their ferment, and yet little, if any, otherwise changed, so that they can be examined under conditions hitherto impossible.

Not the least value of the new method lies on the practical side. The means hitherto adopted of preparing the so-called pepsin for medical purposes are confessedly clumsy and inefficient. By glycerine we can now extract, without any trouble whatever, a pure palateable peptic liquid, one which apparently will last any length of time. It is, moreover, to be depended on for its peptic powers; any one who has fairly tested by actual experiment the various "pepsines" of commerce, will understand the value of this remark.

M. FOSTER

NITRO-GLYCERINE AND GUN-COTTON

IT may be of some interest at the present moment to give a brief summary of certain comparative experiments undertaken with nitro-glycerine and gun-cotton, with a view to ascertain their respective destructive nature and safety of employment as industrial or warlike agents. As it is occasionally inconvenient to employ a material of this kind in the form of a liquid, a modification of nitro-glycerine, known as dynamite, and which is simply powdered glass or sand saturated with the explosive, was applied in the experiments; the force of the dynamite very nearly equals that of nitro-glycerine, and is of course much more readily handled than the liquid explosive itself. Nitro-glycerine or its compounds are the only agents of this nature that can compete in any way with gun-cotton, either as regards its igniting force or cost of production; and for this reason the experiments with these two materials have been watched with particular interest by military men, and have indeed formed the subject of a special report recently submitted to Government by the Committee on Explosives.

The explosive force of detonated dynamite and the Abel gun-cotton, as the compressed or pulped form of this material is termed, was considered to be about equal, and on this account the investigation was more particularly confined to the methods of ignition of the two substances. Professor Abel had already shown, in his communication to the Royal Society, that gun-cotton detonated only under certain conditions and but by the instrumentality of particular agents. And here it should be borne in mind that there exists a very great difference between the detonation and inflammation of gun-cotton. A block of the compressed material, for instance, may be set fire to in an ordinary room without the semblance of danger, the cotton burning vigorously and rapidly, it is true, but without any approach to explosion; ignited, however, by means of a small quantity of fulminate of mercury or fulminate of silver, the explosion is of the most violent description. The fulminates above-named are the only ones found to bring about the ignition of gun-cotton in this truly terrible manner; iodide of nitrogen fails to have any effect thereon, and chloride of nitrogen is occasionally successful in doing so, provided it is employed as a primer in sufficient quantity. While, however, gun-cotton is thus very difficult of detonation, except by the use of special means, nitro-glycerine, or dynamite, readily detonates under ordinary circumstances. That is to say, not only do the fulminates above-mentioned secure its ignition, but percussion-cap and other compositions, as also a sharp concussion, inevitably bring about its combustion.

An interesting experiment will indeed show at once the marked difference between the two explosives. Two wooden boxes were filled with compressed gun-cotton and dynamite respectively, and placed in a suitable position at a rifle range, where they could be hit with certainty by small arms. A bullet was fired at each box, and the results were very conclusive; the dynamite detonated in a terrible manner at the shock, while the gun-cotton was merely inflamed, and burned in a rapid but steady manner.

It was further found that in order to secure certain and perfect detonation, it was always necessary to employ a much larger and more powerful detonating fuze (one containing a large amount of fulminate) for the explosion of gun-cotton than was required for nitro-glycerine, proving beyond doubt, therefore, that the latter is much more readily ignited than the fibrous material. This is of course a great safeguard, and added to the fact that under many circumstances of accidental ignition gun-cotton inflames harmlessly and does not detonate, speaks much in favour of pyroxiline. Indeed the use of nitro-glycerine can, according to our best authorities, be applied only within very narrow limits, as, for instance, for blasting and mining purposes, and its employment even in this sphere necessitates very careful supervision.

From this it will be at once seen that the recent prognostications of several of our war correspondents that the Prussians intend to employ dynamite shells in the bombardment of Paris must be entirely without foundation, for, according to the results obtained by the Explosive Committee in this country, the discharge of a nitro-glycerine shell from a gun would be of itself sufficient to bring about the immediate bursting of the arm itself.

ASSOCIATION FOR THE REFORM OF GEOMETRICAL TEACHING

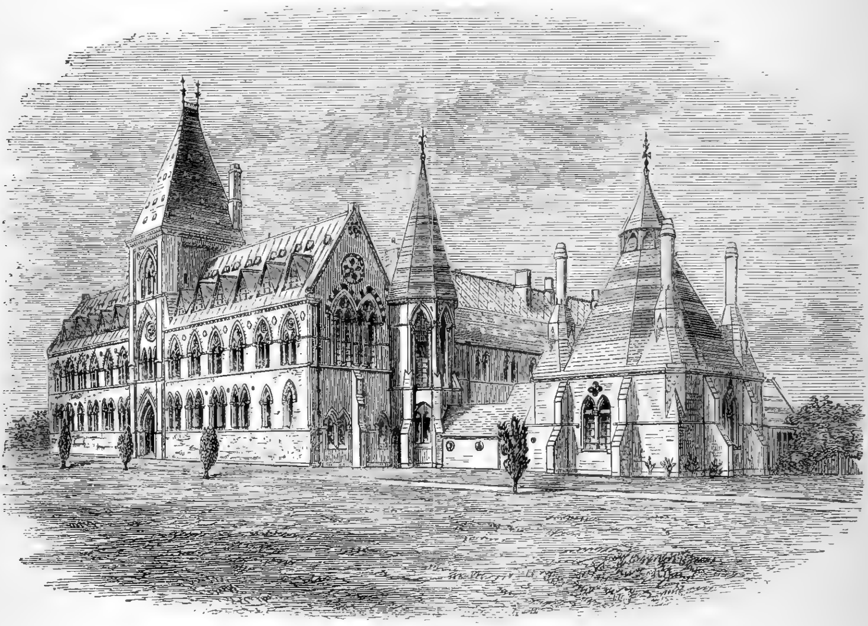
THE following circular has just been issued:—"For sometime past an effort has been made to improve the teaching of Geometry in English schools. The undersigned --all mathematical teachers--are of opinion that good would result from the formation of an Association for the Reform of Geometrical Teaching, and are desirous to elicit the opinion of others who may be interested in the movement. The objects of such an Association would be—1. To collect and distribute information as to the prevailing methods of instruction in geometry practised in this and other countries, and to ascertain whether the desire for change is general. 2. To use its influence to induce examining bodies to frame their questions in geometry without reference to any particular text-book. 3. To stamp with its approval some text-book already published, or to bring out a new one under its own auspices. Should you be willing to become a member of such an Association, you are requested to send your name and address, with a small subscription to meet the necessary expenses of printing advertising, &c., to Mr. Levett, King Edward's School, Birmingham. (Signed) Rawdon Levett, M.A., Senior Mathematical Master, King Edward's School, Birmingham; E. F. M. MacCarthy, M.A., Second Master, presiding over the Modern Department, King Edward's School, Birmingham; J. M. Wilson, M.A., late Fellow of St. John's, Cambridge, Mathematical Master of Rugby School; Robert Tucker, M.A., late Scholar of St. John's College, Cambridge, Hon. Sec. London Mathematical Society, and Mathematical Master, University College School."

A Conference is intended to be held on the 17th of January, 1871, at 2.30 P.M., in the Mathematical Theatre, University College, London, Dr. Hirst in the chair, for the following purposes:—The Association will first be organised. The following resolutions will then be proposed: 1. "That the main object of this Association is to induce all conductors of examinations, at which pupils who have been trained under different systems present themselves, to frame their questions independently of any particular text-book; and that with a view to this object, the members present at this meeting do pledge themselves to use every effort to increase the numbers and extend the influence of the Association." 2. "That with a further view of extending the influence of the Association, local secretaries be appointed for different parts of the kingdom, whose office it shall be to collect information, to make the objects of the Association more generally known in their immediate neighbourhood, and to communicate on all matters of interest with the Central Committee." 3. "That the local secretaries, *ipso facto*, be members of the committee of management." 4. "That all members of the Association shall collect information with regard to text-books and methods of teaching geometry in England and other countries, and that such information shall be forwarded to any secretary or local secretary of the association." 5. "That the committee of management shall, from time to time, print and circulate among others such information as they may consider valuable." 6. "That this meeting is of opinion that in any new text-book—(*a*) the following principles, only partially or not at all recognised by Euclid, should be adopted:—(i) hypothetical constructions, (ii) the arithmetical definition of proportion, (iii) superposition, (iv) the conception of a moving point, and of a revolving line; (*b*) the following limitations should be removed:—(i) The restriction of the number of axioms to those only which admit of no proof, (ii) The restriction which excludes all angles not less than two right angles; (*c*) modern terms, such as locus, projection, &c., should be introduced. These points will be voted upon in detail.

NATURAL SCIENCE AT OXFORD

THE progress which Natural Science has made at Oxford within the last few years has far exceeded the anticipations of even the most sanguine of its promoters. It is but ten years ago that the New Museum was opened, and not much longer since the School of Natural Science was founded. Since then, year by year, the interest shown in these studies has steadily augmented, the number of undergraduates attending the University College Science Lectures has augmented in proportion as the number of these lectures has increased, and the School of Natural Science has become recognised as on a par with the other three great schools of Philosophy, Mathematics, and Law and Modern History. This has been chiefly brought about by the high standard of excellence required by the examiners in this school. When the position taken by Natural Science at a university which has commonly been condemned for neglecting this very subject, is fully recognised outside its own walls, there can be no doubt but that a far greater number than at present will come up to Oxford to pursue their science studies there. Hence it may not be here out of place to give as briefly as possible a short *résumé* of the opportunities held out to Natural Science students at Oxford, in the way of university and college lectures and the various scientific museums and libraries, as well as to notice the numerous rewards and honours which are open to all such students. To do this completely would far exceed the limits of this article, so that what follows must only be taken as a sort of index, as accurate as possible, to a subject, the details of which can be obtained by writing to the tutors of the various colleges mentioned.

Taking the rewards and honours first, we would notice



THE MUSEUM AT OXFORD

that the following colleges award scholarships and exhibitions for Natural Science, after an examination combining both book-work and practical work in any one or any two of the three great branches of Natural Science, Chemistry, Physics, and Physiology.

Balliol—one of 75*l.* every alternate year; one to be given in 1871.

Merton—one of 80*l.* and one or two exhibitions every year; no limit to age.

Christ Church—one of 100*l.* every year; age not to be above twenty.

Magdalen—one of 75*l.* and one or two exhibitions every year; age not above twenty.

Jesus—one of 80*l.*, generally every year; no limit as to age.

New College—one of 100*l.* occasionally.

Queen's—one of 75*l.* occasionally.

Lincoln—one of 60*l.*; a closed scholarship generally given to Owens College students.

There is but little doubt that many of the other colleges will give similar scholarships as time goes on.

But far greater rewards than these are the various fellowships, of from 150*l.* to 300*l.* per annum, which are open generally one or more every year, either for Natural Science alone or for Natural Science combined with Mathematics. These fellowships are awarded after a competitive examination, and are open to those who have taken their B.A. degree; and, unlike the system in vogue at Cambridge, they are open to all members of the University, and are not confined to the members of the particular college which offers the fellowship. Fellowships have been given for Natural Science at the following colleges: Merton, Pembroke, Wadham, and Oriel, and, we believe, at Queen's and Magdalen, and one is to be given next February at Brasenose for Mathematics or Natural Science. It may not be superfluous to add that those who do not succeed in obtaining such a high reward as a fellowship, if they have taken a first class in the Natural Science School at Oxford, rarely fail to obtain valuable appointments after taking their degree, as Natural Science masters or lecturers at various colleges and public schools, whilst some are induced to stay up at Oxford as demonstrators and assistants to the professors, or else as college lecturers or private tutors.

In addition to the purely college rewards just mentioned, the University offers the following valuable emoluments, the first two only open to those who have taken their B.A. degree. The Radcliffe travelling fellowship, of the value of 200*l.* a year, and tenable for three years, of which eighteen months *must* be spent abroad, and the holder must be studying medicine and ultimately take his medical degree at Oxford. The Burdett Coutts Geological Scholarship of about 60*l.* for two years. A gold medal for the Johnson Memorial Prize Essay on some Natural Science or mathematical subject, awarded every four years. Various special prizes for essays, &c., given to the University by various benefactors.*

In addition to these, all the various open University Scholarships and prizes, so numerous at Oxford, are, of course, open to Natural Science students as to all others.

Every term, speaking generally, courses of lectures are given on the following subjects :—

Chemistry, by Prof. Sir B. C. Brodie, Bart., F.R.S.; Physiology and Zoology, by Prof. Rolleston, F.R.S.; Geology, by Prof. Phillips, F.R.S.; Physics (Heat, Light, and Electricity), by Prof. Clifton, F.R.S.; Botany, by Prof. Lawson, M.A.; Zoology (Invertebrate), by Prof. Westwood, F.R.S.; Mineralogy (occasionally), by Prof. Maskelyne, F.R.S. These lectures are open free to all undergraduates.

Lectures are also given at various Colleges, as at Christ Church, on Chemistry (advanced), by Mr. Vernon Harcourt, F.R.S.; on Physics and Mechanics, by Mr. Reinold; and on Physiology, by Mr. Thompson; at Merton on Chemistry (theoretical); at Magdalen on Physiology and Chemistry; at Wadham on Physics and Mechanics, which are open free to the members of the respective Colleges, and on payment of a small fee to others.

In addition to these lectures, a large amount of practical work is made an absolute necessity for a degree in the Natural Science School. Every opportunity for this practical work is given at the Museum, where, under one roof, all the various splendid collections of comparative anatomy, geology, mineralogy, and instruments for experimental, physical, and chemical science are collected together, and are made available for instruction. It is here also that all the University lectures are given, with the exception of those on Botany, which are given in the Botanical Museum in the Botanic Gardens. The illustration on the opposite page is from a photograph of the Museum taken before the building of the New Physical Laboratory. It would occupy far too much space in the present article to describe the contents of this Museum, adequately. Suffice it to say that on the left-hand side are the rooms occupied by Professor Rolleston, for practical work at physiology and comparative anatomy and osteology, fitted up with every convenience, and freely communicating with the general collection of specimens on these subjects placed in the Central Court. On the opposite side are the rooms and collections of Professor Phillips in geology and mineralogy, and above these in the gallery the magnificent collection of insects and invertebrata under the superintendence of Prof. Westwood.

* Thus a prize of 50*l.* was awarded last year for an essay "On Longevity" by an anonymous donor through the University; and a prize of 100*l.* is now offered for an essay to refute the materialism of the present age.

The building on the right-hand side, built apart from the Museum, but connected with it by a narrow passage, is the chemical laboratory. On the opposite side of the central building, not shown in the illustration, is the fine building lately erected as a physical laboratory for Professor Clifton. This building, which is the most perfect physical laboratory in the world, was only opened this term. The collection of physical science apparatus is very valuable, most of it having come from the last Paris Exhibition.

There is every facility given at the Astronomical Observatory for a practical acquaintance with astronomical instruments and methods of observation. There is a good chemical laboratory at Christ Church, as well as one at Magdalen, where, also, the valuable collection of fossils and minerals of the late Dr. Daubeny is open to all working at these subjects. Magdalen, also, has a very good astronomical telescope, and various modern meteorological instruments. A collection of minerals and geological specimens is also in process of formation at Merton. The Botanic Gardens contain every requisite for the thorough study of botany, and in the Museum in connection with it, is a very large and valuable herbarium containing collections of plants for every quarter of the globe.

Lastly, we have to mention what will ultimately tend as much, if not more, than anything else, to make Oxford the great home of Natural Science in the future. We allude to the splendid Radcliffe Scientific Library in the Museum. This Library occupies one side of the building, and consists of two great rooms each 80 feet long, 24 feet wide, and 20 feet in height. It contains the finest collection of scientific books almost in the world, certainly the most accessible. The importance and value of this fine Library cannot be over-rated. Connected with the Bodleian and the Radcliffe Libraries, it contains, as far as possible, complete sets of all the Transactions and Publications of every recognised Scientific Society in the world, and all the new scientific works are added as soon as published. Admirably arranged, admirably managed, freed from all narrow restrictions as to admittance, and open daily from ten to four, and twice a week in the evening from seven to nine, every possible facility is given to those who are working at Natural Science. We do not hesitate to say that until such libraries are founded in other places, Oxford cannot help becoming the great centure of scientific culture in England.

J. P. EARWAKER

NOTES

UNFORTUNATELY the weather does not appear to have been very favourable for the observation of the Eclipse in Sicily. The following telegram has been received from Mr. Lockyer, dated Catania, December 22, 9.40 P.M. :—"Observations of eclipse greatly interfered with by unfavourable weather, but substantial results have been secured. A definite [contact?] of the corona was noticed at a height of about one-third of radius as presented for corona. The sphero-spectroscopic method for first contact was successfully employed. The American observations of last year upon the corona are confirmed." The Astronomer Royal has received the following telegram, which was despatched by Lord Lindsay immediately after the Eclipse. Lord Lindsay's place of observation was La Maria Louisa, which appears to be near Puerto, the mainland station opposite Cadiz :—"Photographs successful. Two good pictures of corona. Polariscope doubtful. Sketching good. Corona [gives] continuous spectrum, no lines. Broken sky." From telegrams received from other members of the expedition, it is hoped that the weather may have been more favourable at the more westerly stations. At Oran, however, we hear that dense clouds covered the sky for twenty minutes before the period of totality; and till after it was over. The previous day there had been a gale of wind.

DR. RUSSELL, Lecturer on Chemistry at St. Mary's Hospital, has been appointed to the Chair of Chemistry at St. Bartholomew's Hospital, lately occupied by Dr. Matthiessen; who also, up to the time of his appointment at St. Bartholomew's, filled the Chair at St. Mary's.

DR. HENRY E. ARMSTRONG has been appointed Professor of Chemistry at the London Institution, an office once held by Mr. W. R. Grove, Q.C., F.R.S., and subsequently by Mr. J. Alfred Wanklyn. Dr. Armstrong studied chemistry under Professors Hofmann, Frankland, and Kolbe, and has been associated with Dr. Frankland and the late Dr. Matthiessen in original researches. The *Pharmaceutical Journal* states that this appointment is connected with a project for establishing practical chemistry classes in the laboratory of the London Institution.

THE American scientific journals record the death, in his twenty-ninth year, of Edward W. Root, Professor of Chemistry in Hamilton College, a pupil of Schneider, Rose, and Bunsen; From his grasp of mind, power of organisation, and clearness of enunciation of scientific truths, he was one of the most promising of the rising generation of chemists in America.

THE days named for the reception of the different classes of objects at the Annual International Exhibition for 1871 are as follows:—Machinery, February 1, 2, 3, 4; scientific inventions, Feb. 6 and 7; educational works and appliances, Feb. 8 and 9; pottery and raw materials, Feb. 10 and 11; woollen and worsted fabrics and raw materials, Feb. 13 and 14; sculpture not applied to works of utility, Feb. 15 and 16; paintings applied to works of utility, Feb. 17; sculpture applied to works of utility, Feb. 18 and 20; engraving, lithography, photography, &c., Feb. 21; architectural designs, drawings, and models, Feb. 22; tapestries, carpets, embroideries, &c., Feb. 23; designs for all kinds of decorative manufactures, Feb. 24; copies of pictures, mosaics, enamels, &c., Feb. 25; paintings not applied to works of utility, Feb. 27 and 28.

THE Royal Horticultural Society's meetings and shows at South Kensington for 1871 are fixed to take place on the following days, namely, on Wednesdays, January 18, February 15, March 1 and 15, April 5 and 19, May 3 and 17, June 7 and 21, July 5 and 19, August 2 and 16, September 6 and 20, October 4, November 1, and December 6. The date of the great provincial show at Nottingham, originally fixed for June 13—17, has been altered, and it is now arranged that it shall commence on June 27, and continue till July 1. The principal meetings at South Kensington will be those on March 15, April 19, May 17, June 7, and July 5, the latter being the National Rose Show

THE days fixed for the Exhibitions of the Manchester Botanical and Horticultural Society, in the gardens at Old Trafford, next season, are, we understand, as follows:—The National Show, now become one of the most important events of the year, will commence on May 26, and continue till June 2; this will include the Royal National Tulip Society's Show on May 26, 27. In addition to this, a great Exhibition of American plants will be made by Mr. Anthony Waterer, of Knap Hill, the period extending from May 26 to June 17, and an Exhibition of Roses and Fruits will take place on July 7, 8.

THE Royal Botanic Society has just issued schedules for its two spring shows in 1871, which are each to be of two days' duration, and are fixed to take place on March 22, 23, and April 12, 13. As usual, new plants and plants of economic interest are admissible, though not scheduled. The Society's summer shows are announced for May 25, 26 (Thursday and Friday), June 14, 15, and July 12, 13 (Wednesday and Thursday).

A DISCUSSION having been carried on in the French Institute on "Winds," M. de Fonvielle sent to the Secretaries a quotation from the works of the celebrated philosopher, M. Mariotte, the author of the "Law for the Expansion of Gases," explaining the fall of pressure noticed during the south-western winds by the direction of the aërial stream which blows from the lower parts of the atmosphere to the higher. He says, moreover, that winds coming from northern quarters descend instead of ascend, and he accounts in this manner for the augmentation of pressure. This note was published in the *Comptes Rendus* at the time.

M. GAUTHIER-VILLARS, the scientific publisher, has completed the publication of Father Secchi's work on the Sun. It comprises more than four hundred octavo pages, and will certainly be largely circulated when Paris is open. Father Secchi has written it in French, having secured the assistance of some learned Jesuits. It is not, however, merely a translation of his former Italian work on the same subject.

A CORRESPONDENT of the *Gardener's Chronicle* has forwarded to that paper the following account of the condition of some of the nurseries near Paris, dated "Châtenay, Dec. 4, 1870.—I am sorry I have but sad news about the establishments; they are all deserted, and the magnificent collections are perishing. In detail I can only report of the establishments of MM. Croux and Durand Fils; the others near Bagneux, Châtillon, and Bourg-la-Reine we only passed several times at night, when marching to the batteries in course of erection, for the staying there during the daytime is not very agreeable on account of the shells from Vanvres, Montrouge, and Bicêtre. M. Croux's principal establishment at Châtenay is the quarters of the Staff of the Bavarian Artillery; the large Palm-house, sixty to eighty feet long, is occupied by the horses, the flower-tubs being made use of for cribs; the magnificent Conifers (Wellingtonias, Pinus Pinsapo, &c.), of which we found numbers of fine specimens, have all been cut down to form a fence along the road to Fontenay-aux-Roses, to prevent the French from having a look into our batteries from their forts. But the most sad sight is offered by the Jardin pour les études pomologiques, belonging to M. Croux, and situated near Aulnay. The beautifully trained fruit trees, after having been much broken by the pulling out of the wires, which were used for making gabions, are now completely eaten down by the 2,000 sheep and 80 to 100 cows shut up in the garden. Nor have the nurseries in the open field been spared; the stems of the young trees had to serve as stakes for gabions, while the branches were used for fagots. A similar sad sight is afforded at the branch establishment of M. Durand Fils, near Clamart; the greenhouses being, to a great extent, demolished by shot coming down here as thick as hail, and the plants they contain are dried up or frozen, for we had $-6°$ R. $= 18°$ F. the day before yesterday, and yesterday morning a considerable fall of snow. It will be about the same with the other establishments not visited by me, and it may be taken for granted that the losses of these people are beyond replacement, and will bring many of them to the grave."

SILLIMAN'S *American Journal of Science and Arts* will, after the close of the present year, become a monthly journal. It was founded by Prof. Silliman in 1818, and now numbers 100 volumes. From its commencement it has been the leading vehicle for the original papers of American scientists.

BRITISH botanists will be glad to learn from Messrs. Longman's lists that Mr. Watson's "Cybele Britannica" may now be obtained from them at the reduced price of 5*s.* per volume. The three parts of the invaluable "Compendium" of the same work are also issued by them in one volume at 10*s.* The author considers that this "must largely supersede the usefulness of the original work," of which he still invites any possessor "to apply to him for a free copy of the Compendium as a necessary supplement thereto." He has already sent a copy to all the possessors of the four volumes with whose addresses he is acquainted.

DR. BUCHANAN, the Professor of Physiology in the University of Glasgow, has just published the third part of his "Essays on the Forces that carry on the Circulation of the Blood." The present part is engaged with the consideration of the Pneumatic Forces. He is of opinion that the ordinary acts of respiration powerfully influence the current of blood in its passage through the whole vascular system. In proof of this he adduces the collapse of the large veins of the neck observed during inspiration, and the fulness during expiration, the former of which phenomena he attributes to the tendency to a vacuum existing in the chest, and the pressure of the external air which empties the great veins of their blood and forces it into the chest; whilst the latter he considers to be due to the fact that, after the termination of an inspiration, no more blood, or very little, enters the chest till the beginning of the next inspiration, and the consequence is that the blood propelled onward by the force of the heart accumulates in the veins near the chest to an extent proportionate to the length of the interval. Again, in order to show that the influence of the respiration extends to the arterial system, he refers finally to the united testimony of all physiologists, who are agreed that the pulse is less voluminous and feebler during inspiration, whilst it recovers its volume and strength during expiration and the period of repose; and, secondly, to the movements of the brain when exposed by removal of the part of the skull. Dr. Buchanan draws attention also to the oscillations of the hæmastatic column observed by Hales, which are clearly associated with the respiratory acts; to the phenomena of asphyxia, and those of the fœtal circulation; the difficulty respecting the latter he ingeniously turns in his favour, by maintaining that, inasmuch as no movements of respiration take place here, the absence of this help to the circulation is supplied by the free communication existing between the right and left sides of the heart, whereby both ventricles are able to exert their influence in maintaining the system in circulation.

THE valuable museum at Brighton is being utilised by the delivery of conversational lectures in the geological, entomological, antiquarian, economical, and sanitary departments. The object is to explain the specimens, and we learn from the *Brighton Examiner* that the plan has been well carried out and has proved very attractive.

GUSTAV ROSE, one of the veterans of German geology, celebrated the 50th anniversary of his doctorate on the 9th inst., when the learned societies of Berlin sent delegates to offer him their good wishes and congratulations.

THE *British Medical Journal* prints the following as an appropriate pendant to the condemnation of tobacco by Kerckringius, cited in our issue for December 8, by John Allen, M.D., F.R.S., on the Evils of Alcohol (*Synopsis Universæ Medicinæ Practicæ*, Amstelodami, MDCCXXX, cap. xvi.) "There remains another sort of poisons, such as vinous spirits and intoxicating distilled liquors. The frequent and excessive tippling of these, as is the practice of each returning day, hath destroyed myriads of mortals, nay, hundreds of thousands more than all the poisons put together; whence I am wont to style this most pernicious evil emphatically THE HARM. It proves not only the parent of very many, and those the worst of diseases, but to numbers suddenly fatal; upon which accounts, if it deserve not the appellation of poison, I must confess I know not what does. Spirit of wine, taken inwardly, is death to almost all creatures; to vegetables of all denominations without exception, when applied by way of pabulum, even to the parent vine, whence itself is derived. The generous physician hath an unpleasant task upon his hands. Men addicted to these spirituous liquors abominably sacrifice day, night, and themselves, to continually sipping, as it were, a liquid fire. When all digestion is lost, the solids unbraced, the juices corrupted; when the human fabric, which hath been long tottering, is just falling to the ground—then are we called in to its support. What must we do? Even as town-scavengers (*scabini*); and ten to one but, after all the abandoned sot returns at once, like a sow that is washed, to wallowing in the mire. Thus he irrevocably prostitutes his health to the last, being prodigal of that life of which he ought to be most tender; and his early end is the consequence of intemperance. What advantageth then the doctor, and what the divine? Fruitless would be the endeavours even of a Luke himself in both his capacities, either as physician or as evangelist. Deaf as a rock to all counsel or persuasion, he runs into the very arms of death, and courts destruction. To this he is prompted by an eternal thirst, which he greedily indulges; and the greater the indulgence, the greater the thirst—the thirst of those pernicious distilled liquors, with which the tragic scene is expeditiously closed; and the dismal catastrophe, in the last moments, is the finishing both his bottle and himself."

A CORRESPONDENT in Honolulu, after making a botanical tour in the Kaala range, says, "Botanising on this island is not without considerable danger. Only imagine descending a steep decline of 70°, which had to be done chiefly by swinging from the roots of one tree to the branches of the next one below, and that at a height of 2,000 feet above the deep gorge beneath our feet." Nature, however, seems in all cases to provide a reward for her admirers, who voluntarily expose themselves to such dangers for the purpose of bringing to the eye of science her numerous hidden beauties, for the writer continues to say, he was not a little surprised by the discovery of a violet with splendid snow-white waxy flowers, some of which were almost half an inch in diameter and exquisitely perfumed. He considers it probably a variety of *Viola chamissoniana*, which he found in its ordinary state lower down in the forest; but the pure white flowers stretching out their long peduncles above the surrounding low undergrowth, and luxuriating in the full sunshine of an azure blue sky, far exceed in beauty those of *V. chamissoniana*, which are of the ordinary violet colour.

FROM the notes of a short tour through the eastern parts of the provinces of Echigo, Iwashiro, and Uzen, made in June and July of the present year by one of H.M. Consuls in Japan, we extract the following:—"In passing through Yazawa and some other villages, we found hemp, said to be of good quality, grown in frequent localities on the way, and vegetable wax trees in abundance. I was informed at Tsugawa that the extraction of lacquer from the same tree is prohibited there, the tree being reserved for the production of wax. As the lacquer is obtained by making incisions in the bark of the tree while young, the result of which is the death of the tree before coming to full maturity, both products can hardly be obtained from the same tree. This appears to be the reason for the prohibition. At Yonezawa, on the other hand, the extraction of lacquer from the tree is permitted, the result of which is, that little vegetable wax is produced there. I observed that many of the trees in the neighbourhood of Tsugawa had been injured, apparently, by the severity of last winter." The trees here alluded to are those belonging to the genus *Rhus*. The most important wax-producing species in Japan being *R. succedanea* L., the bulk of the varnish being yielded by *R. vernicifera* Dec. The wax is obtained from the small fruits, while the varnish is procured by tapping the trees. The species met with at Tsugawa must have been *R. succedanea*, as this species yields both wax and varnish. Several other species also yield varnish more or less in China and Japan. Little is known about the preparations of this varnish as used in the ancient lacquer work of the Japanese; and it is said that the modern workers in this article in Japan have themselves lost the secret of its preparation.

EARLY MENTION OF THE AURORA BOREALIS

THE explanation given by Mr. G. Henry Kinahan* of the superstition prevalent in Ireland regarding "showers of blood" is extremely interesting, and to a great extent the true one; but any student of Irish history must feel how difficult it is to apply it to the interpretation of not a few prodigies recorded in the earliest chronicles. The word "blood" is frequently met with in accounts of wars, in such a manner as to make it quite impossible to construe it into an allusion to the Aurora; nor is it in many places capable of a dual meaning, for instance, the "Chronicum Scotorum"† under A.D. 531, says, in relating the drowning and burning of Muircertach Mac Erca,—

> The king, Mac Erca, returns
> To the side of the Ui Néill;
> *Blood reaches girdles* in the plain;
> Territories increase afar.

Mac Erca was killed by a fairy woman named Sín. The words "Blood reaches girdles" are not very clear, but the Aurora cannot be meant. Under an earlier date it is related (A.D. 497)—

> The battle of Seghais—
> A certain woman caused it;
> *Red blood* was brought over lances
> By Duisech, daughter of Duach.

The further we go back, the obscurer it becomes, and the greater the difficulty in attaching a consistent meaning, especially such an one as a record of auroral appearances. In Dr. Lynch's "Cambrensis Eversus," vol. i., it says:—

"A.C. 673.—Fionachta succeeded his father in the throne. During his reign an enormous quantity of wine fell like fleeces of snow from the sky."

"A.C. 561.—Elim Ollfinachta . . . . succeeded . . . . He was called Ollfinacha, because snow, which fell during his reign, tasted like wine."

The first of these quotations might be explained by saying that an Aurora was visible during the falling of snow, which appeared red from reflection, but this will not do for the second. Under A.D. 604 (Chron. Scot.) occurs—

> Great was the *red sorrow*
> Over the chieftains of Erinn all—
> Aedh Slaine, with multitudes,
> Aedh Roin, Aedh Buidhe, were slain.

Here *red* sorrow means a "bloody sorrow," but I cannot see in this any reference to an Aurora.

For a more direct and satisfactory record of an auroral appearance, the following are given in Chron. Scot.:—

"A.D. 659; A.D. 660—Darkness on the Kalends of May, at the ninth hour; and in the same summer the sky was seen to burn."

"A.D. 670.—. . . . A thin and tremulous cloud, in the form of a rainbow, appeared at the fourth watch of the night of the fifth day before Easter Sunday, stretching from east to west in a clear sky. The moon was turned into blood."

"A.D. 680.—. . . . Loch nEchach was turned into blood." Perhaps this was caused by reflecting the colour of an Aurora.

The "Anglo-Saxon Chronicle" contains the next later observation:—

"A.D. 685.—This year it rained blood in Britain, and milk and butter were turned into blood.‡ The Chron. Scot. follows with:

"A.D. 688.—The moon was turned into the colour of blood on the festival of Saint Martin (11th November)." This is singularly corroborated by the "Brut y Tywysogion" (The Chronicles of the Princes.)§

"A.D. 688.— . . . . it rained blood in the island of Britain, and in Ireland."

"A.D. 689.— . . . a battle against the son of Penda. Bloody rain fell in Lagenia." (Chron. Scot.)

"A.D. 690.— . . . the milk and butter turned to blood." (Brut y Tywy.)

"A.D. 692.— . . . the moon turned of a bloody colour. (Brut y Tywy.)

We now come to a most perplexing record of phenomena, which cannot, I am afraid, be explained; they occurred in

"A.D. 714.— . . . it rained a shower of honey upon Othan Bec; a shower of silver upon Othan Mór; and a shower of blood on the Foss of Laighen." (Chron. Scot.)

If the shower of blood means an Aurora, what do the other showers mean? What is a shower of honey?

The auroral hypothesis will not satisfactorily apply to the following:—

"A.D. 734.— . . . This year the moon was as if it had been sprinkled with blood." (Anglo-Sax. Chron.)

But it may to the following:—

"A.D. 744.—This year a *red* crucifix appeared in the heavens after sunset." (Flor. Wor. and in Anglo-Sax. Chron., under A.D. 743.)

An Aurora is undoubtedly meant in the next record:—

"A.D. 793.— . . . This year dire forewarnings came over the land of the North-humbrians, and miserably terrified the people; these were excessive whirlwinds and lightnings, and *fiery dragons* were seen flying in the air."* (Anglo-Sax. Chron.)

This may be taken as the *earliest direct mention* of an Aurora Borealis in England. "Fiery dragons" are not more inapplicable to the phenomenon than the term "merry dancers," till very lately used in the Orkneys.

The next mention of "blood," whether as a celestial phenomenon or not, I shall leave for others to say is:—

"A.D. 811.—This year was a year of prodigies. . . . . It was in it, also, cakes were converted into blood, and blood used to flow from them when being cut. . . ." (Chron. Scot.)

Digressing for a moment, I am here reminded of what an Irishwoman told me. She said that in Ireland a man, for masticating the sacramental wafer, had a flow of blood from his mouth until he was well-nigh drowned. This blood-tradition seems not to have entirely lost its hold on the Irish peasantry, although appearing in so many garbs.

A *column of light* is recorded to have appeared, but very few will accept it as an Aurora Borealis:—

"A.D. 819.—. . . . heaven afterwards revealed the deed by means of a column of light." (Florence of Worcester.)

"A.D. 850.—. . . . a column of light shot up to heaven, and remained visible to the inhabitants of that place [Repton] for thirty days." (Flor. Wor.)

The next in chronological order is:—

"A.D. 866.—Loch Lebhinn was changed into blood, so that it became clots of gore, like the lights of animals, all round its edge." (Chron. Scot.) I may here remark how difficult it is to say what this record really means, especially when it states that the Loch became "clots of gore."

"A.D. 878.—It rained a shower of blood, which was found in lumps of gore, and blood on the plains of Ciannachta. . . ." (Chron. Scot.)

Perhaps the following may refer to an auroral appearance:—

"A.D. 890.—The heavens appeared to be on fire at night on the Kalends of January." (Chron. Scot.) But not so the next:—

"A.D. 898.—Aideidh . . . [was slain] in treachery . . . . a shower of blood was shed in Ard-Ciannachta." (Chron. Scot.) This looks very much like a repetition of A.D. 878.

The next observation does not occur till

"A.D. 938.—The sun was of the colour of blood, from the beginning of one day to the middle of the day following." (Chron. Scot.) I shall not attempt to say what this was caused by, as I cannot conceive the *sun* being visible during the *night*. The Chronicles I have had access to do not mention the word "blood," nor any miracle connected with natural phenomena since this date, that would afford the least ground for surmising that an Aurora Borealis was meant, till

A.D. 944.—When it records:—"Two fiery columns were seen a week before Allhallowtide, which illuminated the whole world." (Chron. Scot.) Knowing under what various forms Auroras appear, it may not be at all extravagant to suppose this "fiery column" to have been such a phenomenon; however, this is not so convincing as the next on record:—

"A.D. 979.—That same year was seen a *bloody* cloud, oftentimes in the likeness of fire; and it was mostly apparent at midnight, and so in various *beams was coloured*. When it began to dawn, then it glided away." (Ang.-Sax. Chron.)

* See NATURE, December 8, 1870.

† Published under the direction of the Master of the Rolls. Translated by W. M. Hennessy, M.R.I.A., 1866.

‡ Showers of Blood are mentioned as having taken place in Tit. Liv. Book 42, Sect. 20. It says: "There was a report of its having rained blood for three days at a town in Italy." And in Pliny, Book 2, Chap. 56, "It rained blood when M. Acilius and C. Persius were Consuls."

§ Published under the direction of the Master of the Rolls. Translated by the Rev. John Williams Ab Ithel, M.A., 1860.

* In "The Philosophical Grammar" by Benj. Martin, 1738, there is given a list of fiery meteors, and among them are the various forms of the Aurora Borealis:—"*Ignis Pyramidalis*, the pyramidal fire, when it resembles a pillar of fire standing upright; *Draco Volans*, a flying dragon, when the middle parts be thicker and broader than the ends; *Capra Saltans*, a skipping goat, when it appears to have a skipping motion, to be sometimes kindled and sometimes not." (Pages 204, 205.)

Florence of Worcester mentions it as having been seen in

"A.D. 978.—At midnight [the 18th of the Kalends of May (14th April)], there was seen throughout all England a cloud, which was sometimes of a blood-colour, and sometimes fiery; it afterwards broke out into rays of different colours, and disappeared about daybreak." (Chron. Flor. Worc.)

Gaimar, in his "History of the English," repeats this in the following manner:—

"A.D. 978.—At night, as he [the murdered King Edward] lay in the moat, a heavenly light spread itself there; the light was bright (no wonder!) it very much resembled the sun. This ray came over the holy body—the top of it was in heaven."

Putting down 978 as the correct date, and which is confirmed by William of Malmesbury (so far as the death of King Edward is concerned), this year may be accepted as the one in which an Aurora was seen.

From the last date till the year 1052, I cannot find any mention of "blood"-phenomena, or direct references to auroral appearance, and again in this year the evidence is very vague; it says:—

A.D. 1052.—A tower of fire was seen at Ross-Deala, on the festival of St. George, during the space of five hours, blackbirds innumerable going into and out of it, and one large bird in the middle of it." (Chron. Scot.)

The next, still more puzzling, will be my last:—

"A.D. 1103.—In the province called Berkshire, in a place called Heamstede, *blood* was seen by many to flow out of the ground." (Chron. Flor. Worc.)

I think that it will now appear from this account that any attempt to lay down *one* meaning for the whole of the numerous mentions of blood-appearances must fail, although it is, in a few instances, very clear that an Aurora is meant; but it seems as if a distinctive interpretation must be applied to the entries above given. On the whole, it is quite certain that this phenomenon has been seen at very remote dates by the inhabitants of Britain and Ireland; also that the enigmatical "blood"-miracles were not confined solely to Ireland, but seem to have been revealed alike to the *Keltic* inhabitants of England and Wales. I say *Keltic*, because I find the majority of records among the Chronicles to relate more especially to the *Ancient Britons* and *Irish*, and in many cases I believe (as one may judge from the above chronology) the style of poetical descriptions and form of mythical allusions are Keltic. The well-known Druidical Hymns, which appear in old Irish literature, are fair specimens of what I mean. One in particular concludes a mythical story with, "and the third (brother), guided by the lightning from his brother's fingers, shoots an arrow at the swimming hag, who immediately disappears in a *pool of blood*."*

There are two vague poetical descriptions which I imagine to have been suggested by the Northern Lights, in Hesiod's "Theogony," where he describes the war between the Gods and the Giants in the West. (Elton's Translation.)

He says:—

> The gods from Saturn sprung, and those whom Jove
> From subterraneous gloom releas'd to light,
> Terrible, strong, of force enormous, burst
> A hundred arms from all their shoulders huge.
> (Lines 884—887.)
>
> . . . . . Through the void
> Of Erebus, the preternatural glare
> Spread, mingling fire with darkness.
> (Lines 924—926.)

From astronomical calculations this war is stated to have taken place at the autumnal equinox in the year 756 B.C., and to have terminated at the era of Nabonassar; so that such an appearance *may possibly* have assisted Hesiod in composing this poem. The Hindu astronomers also seem to have heard of, or seen a heavenly phenomenon, which I imagine to have been something like an Aurora, if the hypothesis be true, that with the ancients natural phenomena were invariably made the themes of their verse, and were shrouded in allegorical descriptions. The most remarkable passage I have met with occurs in the Mahābhārata, Book i. chap. 15 (Wilkins's Translation):—

"They now pull forth the serpent's head repeatedly, and as often let it go; whilst there issued from his mouth, thus violently drawing to and fro by the Suras and Asuras, *a continual stream of fire*, and smoke, and wind, which, ascending in thick clouds replete with lightning, *it began to rain down upon the heavenly bands*, who were already fatigued with their labour."

* See Thierry, "Hist. de Gaull.," and Pritchard's "Eastern Origin of Celtic Nations."

The date of this supposed war is placed at 945 B.C.

If the foregoing passages be compared with what the "Prose Edda" * says, the hypothesis will not appear unreasonable. In the chapter on "The Twilight of the Gods, and the Conflagration of the Universe," it says:—

> Midgard's protecting ward
> Bravely fights and slays
> The serpent monster.
> Then shall all mankind
> The earth abandon.
>
> Dimm'd 's now the sun,
> In ocean earth sinks:
> From the skies are cast
> The sparkling stars;
> The fire-reek rageth
> Around Time's nurse,
> And *flickering flames*
> With heaven itself playeth.

The idea of "flickering flames" is original, or, at least, not borrowed from the Eastern poets, and, in my judgment, could only apply to the Aurora, it may be an extraordinary appearance of it; and as the Aurora, which has been seen in England this year, was also visible in India, I think it not at all unlikely that "a continual stream of fire," which "began to rain down," is a record of a similar extensive phenomenon.

Dec. 20 JOHN JEREMIAH

* Mallett's "Northern Antiquities" (Bohn's Edition, 1847, p. 455).

BALLOON ASCENTS FOR MILITARY PURPOSES

III.

THE laws of the motion of a balloon, dependent on the change of level, appear to have been hitherto very little discussed from a scientific point of view. It is, however, a motion which can be procured very easily by throwing out a small quantity of sand, or of gas, if the balloon is properly constructed, and which is of great importance for any expedition in time of war, more perhaps than even the attempt at guiding its direction. The number of minutes required for descending from a great altitude as well as for ascending to a certain level, being the most important consideration for the aëronaut endangered by the vicinity of some foreign force, this was analytically examined by M. Dupuy de Lome. It is the first instance that I know of such a disquisition since Euler worked his equations relating to the elevation of an aërostatic sphere supposed to be inextensible, and to be carried away in the atmosphere with a certain amount of motive power due to the small specific gravity of the included gas. That beautiful analytical disquisition is the last ever written by the old philosopher, who was totally blind at the time. It was found written by him on the *tableau noir* where he was making his calculations on the very day before he died. He had received the intelligence of the great experiment tried by Mongolfier, and his excited brain had produced during the night that masterly piece of mathematical skill which was unhappily his last! This contribution to scientific ballooning is to be found in the "Mémoires de l'Académie des Sciences de Paris" for 1781, a date anterior to the experiment of Mongolfier, which is accounted for by the issue of the volumes being always later than the date inscribed on them. Another singularity is that Euler speaks of gas for filling the balloon, while Mongolfier's was merely heated air. We must not, however, give Euler the merit of having been the real inventor of *Charlières* or gas balloon, as Mongolfier believed that he prepared gas by burning damp corn-straw! Before returning to the questions considered by Dupuy de Lome, we may be allowed to mention that the use of gas enclosed in a gasholder of any description, was suggested by Blake in his lectures at Edinburgh, and by an Italian philosopher transacting business in London. Carvalho tried to give to the idea of Blake the shape of an experiment, but uselessly, for the want of a proper varnish, which was invented by Charles a few months only after Mongolfier's great experiment.

The principal difficulty for strangers to the scientific working of an aërostat, appears to be to draw a broad line between the *motive power* or *force ascensionnelle*, and the *space* offered for free dilatation without any gas being lost in the air, which space I will call *the dilatation chamber*, although generally there is no special balloon to allow for this, but the lower part of the balloon is left unfilled.

The *Géant* had a special balloon for this purpose attached to the bottom of the large one by a kind of short connecting tube of a very large diameter, and this balloon was called the *compensator*. The arrangement can be seen by the engravings showing the *Géant* in *aerial travels*.

If we suppose that we have at our disposal a balloon of india-rubber susceptible of any distension, we are in a position to assimilate the motion of our aërostat to the elevation of an *Atwood's Machine* moving upwards with a certain moving weight, without any other friction than that of the air. All the calculations and formulæ worked for that philosophical instrument can be used. a = the weight of the air replaced; b = the weight of the balloon including gas and everything; $\frac{a-b}{a}$ will be the motive power; the motion will take place according to the rule for accelerating powers in a medium where the pressure is diminishing, as is the case with the atmosphere when the balloon is ascending. If we pay no attention to the friction on the air, which is very small indeed when motion is slow, we have an acceleration of motion varying as t, and a height obtained varying as t^2, as is well known. If g' is the new motive power and g the motive power of the ordinary specific gravity, then $g' = g \times \frac{a-b}{a}$; $\frac{a-b}{a}$ remaining constant under the assumption we have given.

The best way to realise this assumption is to suppose that the balloon is partially empty when leaving the surface of the earth, and the assumption holds good as long as the balloon is not filled up by dilatation. The time taken by the dilatation to fill up the space allowed to it, regulates the level where the balloon can ascend without losing any of its motive power. This friction must be considerable in cases where the balloon is to be sent to a great distance from the earth. The chamber of dilatation must be chosen in proportion to that distance. At all events it must be calculated thus: R being the radius of the sphere $\frac{4}{3}\pi R^3$ is the maximum volume which the gas is able to take without escaping into the atmosphere, C being the weight of gas and Δ its gravity for each cubic metre $\left(\frac{4}{\pi} R^3 - \frac{C}{\Delta}\right)$ is the number of cubic metres which can be afforded for dilatation, S_0 H_0 being the actual pressure on the earth. The pressure can be diminished in the proportion $\frac{\frac{C}{\Delta}}{\frac{4}{3}\pi R^3}$ without the gas beginning to escape. If we call H_1 the altitude where this escape is to begin, we can write the equation $H_1 = H_0 \frac{\frac{C}{\Delta}}{\frac{4}{3}\pi R^3}$ To ascertain the actual value of the corresponding altitude, it is necessary to look at the empirical tables inserted in the *Annuaire du Bureau des Longitudes* of each year, and calculated for reckoning the altitude from actual barometric pressure. These tables were calculated by M. Mathieu on the assumption of the truthfulness of Laplace's equations given in his *Mécanique céleste;* but I suspect these assumptions are not sound, and may possibly mislead French aëronauts, while Prussians are watching them below ready to shell their balloon if it comes within range. But having instituted no direct measures for ascertaining the value of this law, aëronauts are obliged to make use of it. The calculations of M. Dupuy de Lome for carrying his intended balloon out of range suppose the truthfulness of the numbers of the *Bureau des Longitudes.* If in doing so aëronauts are not sure of escaping hostile bullets, they can at all events get rid of every analytical obstruction, which is certainly something.

When the escape begins, the motive power is not destroyed at once. It certainly diminishes at a very quick rate if the *appendix* is wide enough to give free issue to the gas, and the vertical motion is also rapid. If not there is some danger of explosion, as can easily be imagined. Generally aëronauts are very anxious to get rid of this danger, which can be done very easily by opening the escape valve. But this operation involves the aëronaut in a "sea of troubles," as the valve for discharging the gas is rendered gas-tight only by the application of a proper plaster. The only way of dealing rationally with that excess of gas is to have a proper vertical motion when the discharge begins. That condition is very easy to obtain if you start with a very small ascensional power indeed.

In the fraction $\frac{a-b}{a}$ is very small, and moreover if the fraction $\frac{\frac{C}{\Delta}}{\frac{4}{3}\pi R^3}$ is large enough, you can conduct your balloon very safely at any distance if you do not meet with dark clouds, or burning sun. You can get rid very easily of these conditions by disposing cleverly of your ballast, as will be very easily understood by everybody after some explanation. There is however a circumstance which is very annoying in our military ascents, and on which it may not be useless to say a few words: the necessity of going at a certain level before reaching the meridian of the enemy's lines. The aëronaut is therefore obliged to know that distance and the quickness of the motion of the wind, so that the fraction $\frac{L}{V}$ gives the number of minutes at his disposal to reach the level required above that dangerous meridian. V = medium velocity of the wind, as obtained by balloons sent free into the air, S = elevation which the enemy's bullets cannot reach, I suppose it to be 6000 yards. Having no proper experiments at my disposal, I beg leave to make that gratuitous assumption. M. Dupuy de Lome, in his contribution, speaks only of 3000 metres, but Krupp's cannon was not in operation when he was writing. L = distance of enemy's lines from the workshop. It is of great importance to increase that distance as far as possible, and I advised the Government to take two starting stations, one from the northern bank to be used when the wind was blowing southerly, and one from the southern when the wind was blowing northerly, so that in every case aëronauts might cross the whole of our city. But the suggestion was disregarded. The solution adopted was to start in the night time! It is a singular mode, very unscientific, to solve an analytical problem by the sending of the aëronauts either to the great ocean to be drowned, or to Norway to be frozen. The subject is far from being exhausted, as to the rebounding of the balloon according to the law of oscillatory motions. But fearing to extend my remarks to a length beyond the patience of my readers, I beg leave to end my contribution at this point, thanking the editor of NATURE for the hospitality exhibited towards a French aëronaut, and hoping to be more fully acquainted with the English scientific public on some future occasion.

W. DE FONVIELLE

SOCIETIES AND ACADEMIES

LONDON

Royal Society, Dec. 22.—"On the Constitution of the Solid Crust of the Earth." By the Ven. Archdeacon Pratt, M.A., F.R.S. In this paper the author applies the data furnished by the pendulum-observations recently made in India, to test the truth of the following hypothesis regarding the Constitution of the Earth's Crust, which he propounded in 1864, viz. that the variety we see in the elevation and depression of the earth's surface in mountains and plains and ocean-beds has arisen from the mass having contracted unequally in becoming solid from a fluid state; and that below the sea-level, under mountains and plains, there is a deficiency of matter, approximately equal in amount to the mass above the sea-level; and that below ocean-beds there is an excess of matter approximately equal to the deficiency in the ocean when compared with rock; so that the amount of matter in any vertical column drawn from the surface to a level surface below the crust is now, and ever has been, approximately the same in every part of the earth. In order to make this hypothesis the subject of calculation, the author takes the case of the attenuation of matter in the crust below mountains and plains, and the excess of matter below ocean-beds, to be *uniform*, to a depth m times the height above the sea-level or the depth of the ocean, as the case may be. The results are shown in the following Table, in which the numbers are the last figures in the ratio of the differences of gravity to gravity itself, carried to seven places of decimals. The decimal point and ciphers are omitted for convenience.

The author points out from this table that Dr. Young's, or the usual method of correction for local attraction, so far from improving matters, introduces very large residual errors of the arc and ocean stations; and, at places on the arc of meridian, all lying on the same side with reference to Punnæ. He observes that neither the usual method nor his own much affects the coast-stations, and attributes this to the want of more complete knowledge of the contour of the surface, both above and below the sea-level; in these parts. But his own method, in the case $m = 50$, remarkably reduces the effects of local attraction at stations on the arc of meridian and out at sea (in Minicoy, an island 250 miles west of Cape Comorin or Punnæ); for the sensible negative quantity at Damargidæa and positive quantity at Kalianpur indicate a deficiency of matter below the first and an excess below the second—which exactly tally with the results independently brought out by relative deflections of the plumb-line as obtained by the survey; and the two large and most important effects, negative at Kaliana and positive at Minicoy, may be said to be almost annihilated by this method of correction. This last case of an *excess* of gravity out at sea (where the surrounding ocean has a deficiency of matter) being explained by his method, he regards as a very strong argument in its favour. And he finishes by saying that if his method is thus far successful in the particular supposition of the distribution below, whether in excess or defect, being *uniform*, which is most likely not strictly the case, there is every reason for concluding that pendulum-observations give support to the hypothesis regarding the constitution of the Earth's Crust, when viewed on a large scale, admitting of local peculiarities, like the deficiency of matter near Damargidæa and the excess near Kalianpur, and the similar deficiency near Bangalore.

"On the Extension of the Coal-fields beneath the Newer Formations of England; and the Succession of Physical Changes whereby the Coal-measures have been reduced to their present Dimensions." By Edward Hull, M.A., F.R.S., F.G.S., Director of the Geological Survey of Ireland. In this paper the author, embodying with his own the observations of previous writers on the physical geology of Great Britain, especially those of Murchison, Godwin-Austen, Ramsay, Phillips, and the late Professor Jukes, showed that the Coal-measures were originally distributed over large tracts of England, to the north and to the south of a central ridge or barrier of Old Silurian and Cambrian rocks, which stretched across the country from North Wales and Shropshire into the Eastern Counties, skirting the southern margin of the South Staffordshire Coal-field. This barrier, or ridge, was a land-surface till the close of the Carboniferous period. To the north of the central barrier, the highlands of Wales, the mountains of the Lake district, and probably small tracts of the southern uplands of Scotland, formed land-surfaces skirting portions of the Carboniferous area, while the Carboniferous tract to the south of the central barrier was probably bounded by a land-surface trending along the southern coast of England. The distribution of the Coal-measures at the close of the Carboniferous period was illustrated by a map. It was then shown that the whole Carboniferous area was subjected to disturbances through the agency of lateral forces, whereby the strata were thrown into folds along axes ranging (approximately) in east and west directions; and as denudation accompanied and followed these disturbances, and acted chiefly over the arches (or anticlinals), large tracts were divested of Upper Carboniferous strata, and thus the first phase in the marking out of the limits of our present coal-fields was brought about. The effects of these movements and denudations were illustrated by another map. The disturbances which ensued after the deposition of the Permian strata, and which produced the discordances of stratification between the newer Palæozoic and Mesozoic formations, were shown to have acted along lines ranging approximately north and south, parallel to the axis of the Pennine Chain, and consequently in a direction transverse to those of the previous period. These disturbances were also accompanied by the denudation of strata from off the anticlinal arches, and the consequent disseverance of the coal-measure tracts over certain definite areas. The results of these movements (the second phase in defining the bounds of the coal-fields) were illustrated by a third map. From a consideration of the foregoing observations, the author came to the conclusion that the tendency of the British coal-fields to arrange themselves into the form of "basins" (sometimes partially concealed by newer strata), a tendency strongly insisted on by Professor Ramsay, F.R.S., was due to the intersection of the two systems of flexures above described, one anterior to the Permian period, the other anterior to the Triassic period, and that the actual disseverance of the coal-fields into basins was due to denudation acting with greatest effect along the anticlinal arches of these flexures. The inference that the Yorkshire and Durham coal-fields are really basins rising to the eastward under the Mesozoic strata was drawn—an inference supported by the easterly rise of the coal-measures along the sea-coast from the Coquet to the Tyne. Guided by these principles, the author maintained that we were now in a position to determine with great accuracy the actual limits of the coal measures under the Mesozoic formations over the area to the north of the central barrier ridge, and that to the south of the ridge the application of the same principles would assist towards the solution of the question, though in a less degree, owing to the fewer opportunities for observation of the Palæozoic formations. The author, however, concurred in the views advanced by Sir R. I. Murchison,* that in consequence of the great amount of denudation which the carboniferous rocks had undergone over the area o the south of England previous to the deposition of the Mesozoic formations, little coal was to be expected to remain under the Cretaceous rocks.

Anthropological Society, December 20.—Dr. Charnock, V.P., in the chair. The following were elected Fellows, Mr. H. W. Bellew, Peshawur, India; Mr. F. Tagart, F.R.C.S.; and Mr. C. Cornish Brown. The Rev. W. W. La Barte, M.A., Local Secretary for Brighton. Mr. A. L. Lewis read a paper "On some Archaic Structures, principally Megalithic, in Cornwall and Devon, with remarks on their probable Uses." The author drew a comparison with similar monuments in other places, and illustrated the paper by the exhibition of models, from his own sketches and measurements, and by photographs. The structures described were, a circle called Dance Maen, two circles both called "Nine Maidens," three circles together called the "Hurlers," all in Cornwall; and one on Dartmoor, Devon, all which the author believed to have been used for sacrifice, and compared with some so used in India; "Chun Quoit," a sepulchral dolmen; "Lanyon Quoit;" "the Spinster," Devon; "the Trevethas Stone," Cornwall, used for sacrifice; the "Men-an-Tol," Cornwall, a monument of perhaps a phallic character, and the ancient towns called Chun Castle, Cornwall, and Grimspound, Devon.—Dr. Henry Muirhead contributed some remarks on the Difficulties of the Theory of Natural Selection. The opinions of Mr. A. R. Wallace on the subject were criticised; and the term "survival of the fortunate" suggested for that of "survival

* In his address at the meeting of the British Association at Nottingham, 1866. On the other hand, the views of Mr. R. Godwin-Austen, F.R.S., which tend rather in an opposite direction, should be well weighed by all who are interested in this question.—*Quart. Journ. Geol. Soc.* vol.

of the fittest," adopted by Mr. Wallace from Mr. Herbert Spencer. The subject of individual variation was discussed at some length, and the laws of divergence commented on. The author expressed his dissent from Mr. Wallace's interpretation of Darwin's theory.

Mathematical Society, Dec. 8.—Mr. W. Spottiswoode, F.R.S., president, in the chair. Mr. J. Hamblin Smith, M.A., of Caius College, Cambridge, was elected a member.—Prof. H. J. S. Smith made a communication on the subject of Elliptic Integrals.—Prof. Cayley read a note on his former paper, "On the Theory of the Rational Transformation between two Planes, and on Special Systems of Points," followed by an account of an addendum to his recent memoir on "Quartic Surfaces." In this latter communication he stated the following theorem:—Take any seven points; an eighth point at pleasure on the dianodal surface of the seven points; a ninth point at pleasure on the dianodal curve of the eight points. In the system of nine points so determined take any one as vertex, and joining it with the remaining eight, construct the ninth line of the "ennead": we have thus nine lines passing through the nine points respectively. These nine lines meet in a point which is the "enneadic centre" of the nine points; and further, the ten points form a completely symmetrical system, so that each one of them is the enneadic centre of the remaining nine. [The name "ennead" is given to any nine points *in plano*, which are the intersections of two cubic curves, or to any nine lines through a point which are the intersections of two cubic curves; the ten points in space are such that taking any one whatsoever as vertex, and joining it with the remaining points, the nine lines form an ennead.] The author stated the following system of correspondence as a subject for investigation—viz., given any eight points in space; then to every point in space corresponds a line through this point, viz., the ninth line of the ennead obtained by joining the point with the eight given points respectively; and to each line in space a point or points on the line, viz., the point or points for each of which the line is the ninth line of the ennead obtained by joining the point with the eight given points respectively.—Dr. Hirst entered at some length into an explanation of the methods employed in his paper "on the Polar Correlation of two planes, and its connection with their Quadric correspondence." Profs. Cayley, Smith, Mr. Cotterill, and the author took part in a discussion on the paper.—Prof. Henrici exhibited a large model of Dr. Sylvester's amphigenous surface, which has for its equation

$$JK^4 + 8LK^3 - 2J^2LK^2 - 72JL^2K - 432L^3 + J^3L^2 = 0$$

where
$$K = \frac{D - J^2}{128}$$

The equation of the surface is obtained by substituting $x = 1024\,L$, $y = \frac{2}{3}\,D$, $z = 6\,J$ and taking x, y, z as rectangular cördinates. The unit was taken $= \frac{1}{6}$ of an inch. The sections parallel to the axes of cördinates are unicursal curves. Thus the cördinates x, y, may be expressed and terms of z and a parameter ϕ:—

$$x = \frac{1}{64}\,\frac{1}{\phi^3(\phi + 1)}\,z^3$$

$$y = \frac{1}{64}\left(\frac{\phi + 2}{\phi}\right)^2 \frac{\phi - 3}{\phi + 1}\,z^2$$

The surface is of the ninth order, and has two cusp lines. The one is a common parabola in the plane $L = 0$, and has the equation $K = 0$ or $D = J^2$. It is of the second species, that is to say, any plane section of the surface possesses a cusp of the second species where it cuts it. The second is a common cusp line. It is a curve of double curvature of the third order, and has the equations

$$27\,L = -\,J^3\,;\quad 3\,D = -\,125\,J^2$$

thus the projections on the three axes are a common parabola, a semi-cubic and a cubic parabola respectively. Both cusp lines ouch one another at the origin, where the axis of J is a common tangent; thus the origin is a triple point, as appears also from the equation. The surface divides the whole space into two congruent parts. If we turn the surface through an angle of 180° about the axis of D, which is altogether on the surface, one half will take the original position of the other. The plane $D = 0$ touches the surface along a curve $2048\,L = J^3$, and divides each half of the space, separated by the surface, into three distinct parts. It is this property, which connects the surface in so remarkable a manner with the theory of binary quintics, and by aid of which Dr. Sylvester has shown (Phil. Trans. Part iii. 1864) how to decide whether the roots of an equation of the fifth degree are real or imaginary.

BERLIN

German Chemical Society, November 14.—Alex. Müller reported on the determination of very minute quantities of sulphuric acid in water. His method requires but small quantities of water, and consists in adding to it a weighed quantity of chloride of barium and an equivalent proportion of chromic acid. For every equivalent of sulphuric acid present in the water, one equivalent of chromic acid remains free, and can be determined by colorimetric comparison. He was thus enabled to determine one milligramme of sulphuric acid in fifty grammes of water.—Messrs. Emmerling and Engler have prepared phenyl-methyl-aceton: $C_6\,H_5\text{-}CO\text{-}CH_3$ by distilling together benzoate and acetate of lime. Nitric acid converts this body into two isomeric nitro-compounds of the formula $C_6\,H_4\,(NO_2)\text{-}CO\text{-}CH_3$, one of which is crystalline and the other a liquid. These compounds have acquired an unusual interest in the hands of Emmerling and Engler, serving as they have done for the first artificial formation of indigo blue. Indigo blue having the composition $C_8\,H_5\,NO$, the nitro-compound mentioned $C_8\,H_7\,NO_3$ has to lose $H_2\,O$ and O to yield $C_8\,H_5\,NO$. This it does under the influence of soda and powdered zinc. The transformation is somewhat analogous to the reaction lately described by Baeyer, by which nitrocinnamic acid, $C_9\,H_7\,NO_4$, submitted to the action of powdered zinc, loses CO_2 and O_2 and forms indol, $C_8\,H_7\,N$. It appears that two molecules of nitro-phenyl-methyl-aceton enter into the reaction, and that the formula of indigo blue ought to be doubled, thus:

$$\begin{array}{l} C_6\,H_4.\,CO.\,CH\,[H_2] = \{H_2\}\,HC.\,CO.\,H_4\,C_6 \\ N[O_2] \qquad\qquad\qquad\qquad\qquad\qquad [O_2]\,N \end{array}$$

The elements put in brackets are those eliminated in the reaction, by which apparently the nitro-groups are converted into azo-groups. Nascent hydrogen transforms the azo-groups into the hydrazo-groups, that is to say, the artificial indigo-blue into indigo-white. The latter reaction has been employed to identify the artificial with the natural product.—L. Henry indicated a practical way of forming iodate of potassium, by treating the corresponding chlorate with protochloride of iodine: $K\,Cl\,O_3 + I\,Cl$ gives $K\,I\,O_3 + Cl_2$.—Dittmar and Kékulé have prepared a glycolic acid of the aromatic series. Cymol from camphor was converted into toluylic acid, then into bromotoluylic acid, and by the action of baryta water into oxytoluylic acid $C_6\,H_4\begin{smallmatrix} C\,H_2\,O\,H \\ C\,O\;\;O\,H \end{smallmatrix}$—E. Erlenmeyer has studied the action of cyanamide on the hydrochlorides of compound ammonias, particularly of methylamine. He has thus produced methyl-guanidine, hitherto called methyluramine, and obtained by oxydising kreatine. It appears that crystallographic differences exist between the platinum salts of the artificial and of the natural compound. The same chemist has found that ordinary butylic alcohol yields isobutylic and acetic, but not propionic acid. He likewise communicated researches on the differences of the various valerianic acids.—A. Lieben communicated his views on the formation of chloral-alcoholate, thinking that trichlorinated acetal precedes the formation of the above compound.—A. Bunge reported on the electrolysis of some sulphur compounds.—C. Lieberman has investigated the substance described some years ago by Roussin under the incorrect name of artificial alizarine. It is formed by gradually adding nitro-naphthaline and zinc to sulphuric acid previously heated to 200°. Brown crystals are thus separated, giving colours with alkalies of a different hue from those produced by alizarine, and showing the composition $C_{10}H_6O_4$. It appears to be binoxynaphthochinone, and to stand in the same relation to naphthaline in which alizarine stands to anthracene. He calls the substance naphthazarine; the colours it gives are of no practical interest.—C. Vogel reported on the practical production of oxygen and of hydrogen by the New York Oxygen Gas Company. This company prepared in the month of August 20,000 cubic feet of oxygen a day at the price of five cents a cubic foot. The gas is pressed into copper reservoirs under a pressure of ten atmospheres, and largely used for laboratory and medical purposes, but chiefly for hydro-oxygen lamps in bridge-building under the surface of rivers. In lecture rooms also this kind of illumination is largely used to procure enlarged views of small photographs or drawings made on gelatine. The process for making oxygen is that first used by Jessie du Mothay. Iron retorts are filled with 900 lbs. of a mixture of peroxide of manganese and caustic potash. A current of air passed through the retorts heated to 450°, transforms their contents into manganate. A current of steam is then passed through which sets the oxygen free and leaves a residue of sesquioxide of manganese and caustic potash. These processes may be repeated innumerable times. Hydrogen, together with carbonic acid, is produced on a smaller scale by heating to redness retorts filled with anthracite and hydrate of lime, for fifteen minutes. Afterwards steam is passed through to reproduce hydrate of lime. The same mixture can thus be used for three weeks. The hydrogen is sold at two cents a cubic foot in copper reservoirs holding sixty gallons similar to those described above, which are sold by the company at about eighteen shillings a piece. The sale amounted in August only to 2,000 cubic feet a day, as coal gas is generally used in preference to hydrogen.

November 28.—C. Rammnelsburg reported on the composition of tantalites and niobides. — A. Müller described a furnace for organic analysis.—Fr. Mohr in a lengthy paper tried to refute the laws of Avogadro and all modern theories in general. The same communicated his views on the connection of the conducting power for heat and the molecular movements of gases.—J. Thomson has determined the heat of combustion of hydrogen equal to 340·00. This number stands between those found by Andrews (338·00) and by Farne and Silbermann (344.00). He has also determined the quantity of water yielded by the combination of two litres of hydrogen, and found a number closely coinciding with that given by Stas. The same chemist described an apparatus for showing the combustion of oxygen in an atmosphere of hydrogen and a mode of exhibiting the alternate reduction and combustion of copper.—C. Bender has analysed some combinations of the hydrate and the chloride of magnesium.

VIENNA

I. R. Geological Institute, November 22.—Fr. von Hauer delivered the anniversary address, with a report on the progress made by the Geological Survey during the past year.—Baron Const. Beust gave a description of the layers of zinc and lead ores on the Schneeberg, in Tyrol. Although known for a long time, their real value has never been appreciated. The parts of the bed at present opened contain, after a moderate deduction, ores to the value of more than eighty million florins (eight million sterling). All measures are being taken for an extensive investigation.—M. F. von Hochstetter exhibited miniature volcanoes formed by sulphur in a soda manufactory. Sulphur melted in water under a steam-pressure of two to three atmospheres combines with a certain quantity of water. Larger masses of this melted sulphur (one to two quintals) were poured in conveniently deep wooden vessels. In consequence of the refrigeration, a crust was soon formed on the surface. In this crust a hole was kept open, through which, as the congelation of the sulphur proceeded, periodical eruptions of melted sulphur, together with exhalations and explosions of steam, were observed. After the lapse of an hour and a half, a miniature volcanic cone was formed, with all the characters of a volcano formed by successive lava streams. Observations which can be made during this experiment are sufficient to explain and to confirm many facts observed in real volcanoes. If the artificial eruption is interrupted by a second hole made in the crust, the cone becomes hollow, and if this hollow cone is crushed and the eruption again caused by closing the second hole, a model is formed of a younger volcanic cone which is surrounded by an outer barrier, like Vesuvius or the Peak of Teneriffe. If the process is conducted to the end without interruption, the result is a massive cone with a closed crater, which resembles perfectly the homogeneous dome-volcanoes, as Seebach calls them. These domes, or massive cones, must therefore be considered as the inner massive nuclei of perfectly extinct volcanoes, the lava, ashes, and tuffs of which have been removed by denudation.

BENGAL

Asiatic Society, September 7.—The Hon. J. B. Phear, President, in the chair. "The Vástu Yága and its bearings upon Tree and Serpent-worship in India," by Babu Pratápachandra Ghosha, B.A. The Vástu Yága and various other forms of Serpent and Tree-worship are traceable as much to a feeling of fear as to other causes. It is evidently a sacrifice, invented by the ancient Aryan conquerors with a view to propitiate the aborigines or primeval owners of the land. Vástu is the principal god, and though the aborigines themselves are not worshipped by name, the Nága is no doubt the ostensible object of worship. The several gods, properly *pitris* (ancestors, predecessors, former owners) that occupy the several *mandalas*, are also the names of Nágas. The Vástu is the God Earth, quite distinct from Dhará (Terra) and in the prayer he is represented as the supporter of the world. The Vástu Yága, therefore, appears to be a memorial of the foundation of the new Aryan home and of the Nágas, a powerful race of aborigines. In the ceremony for dedicating a tank, a stick is planted on its banks. This stick is the *Nága-yashti*, or the Nága-pole. The application of the term Nága to the reptile class is without doubt of comparatively recent date, and since that time may be noted the double meaning of the word applied to the Nága aborigines as well as to the Nága serpents. Ananta is worshipped not as a snake, but as a form of Vishnu. It literally means eternity. The *Anantacha-turdas'i*, *Nágapanchami*, and such other minor vratas, though connected with the Nágas, have nothing to do with the actual reptile. The aborigines of India bore a peculiar relationship to the first Aryan settlers. Many of the aborigines were held in high estimation, and in a legend the goddess Sarasvati is described as imparting the art of music to two of the Nágas (*Kamvala* and *As'vatara*), and the name of Karkotaka, another Nága, is enjoined to be uttered every morning, There are again several fruits, trees, and things which are named after the Nágas, and these are all derived from the N.E. frontiers of India. From the above, it would appear that the Nágas as a race of powerful aborigines were respected for their prowess and also hated for their barbarous habits. The eminent among them were soon identified with some Hindu gods, and ultimately the Nágas, as a race, became a class of gods. Serpent-worship, in the true sense of a creature-worship, was never prevalent in India, and though, under peculiar circumstances, this worship may be seen at the present day among the several hill tribes, still such a practice does not obtain among the Aryans. The serpent, as an emblem of eternity, is respected, but it is the worship of Vishnu and not of the reptile. Serpents have crept into our mythological legends, but in whatever form they appear, they are put down as enemies of Vishnu. Ráhu is darkness, and its stellar form is a snake. Sun = Hari = Vishnu, the destroyer of Ráhu, the first destroys as darkness, the second as snake, and the third as death. Figures of Nágas occur in sculptured stones, but only for ornamentation. Several trees are described in later Puránas as forms of Vishnu and other gods, but they are cherished with a degree of care because of their extreme usefulness in the tropical country. For instance, *Tulsi* as an aromatic herb, the *Durva* as a fodder on which the cattle live, the religious fig-tree as offering cool shelter, the cocoa-nut as a refreshing fruit. Some trees again are noted as obnoxious when planted near dwelling houses, because in a Hindu hygienic point of view, they are considered injurious to health. The papaya plant is one of those that no Hindu would like to have near his house.

PHILADELPHIA

Academy of Natural Sciences, Sept. 6. — Mr. Vaux, Vice-president, in the chair.

Sept. 27.—The President, Dr. Ruschenberger, in the chair.—"On the Flowers of *Aralia spinosa* L. and *Hedera Helix*, L." by Thomas Meehan. The study of *Aralia spinosa* L. affords some interesting facts which do not seem to have attracted the attention of other observers. In Dr. Gray's indispensable "Manual of Botany," it is said to be "more or less polygamous." I have had many specimens under my daily observation this season, from the earliest opening till the last blossom appeared, and find that it is much more nearly monœcious than the above quotation would imply. There are three different sets of flowers corresponding to the thrice compounded branchlets of the large panicle. When the flower scape elongates, it seems suddenly arrested at a given point, and a very strong umbel of *female* flowers appears at the apex. A great number of secondary branches appear along this main one ; and they also suddenly terminate each with an umbel of female flowers. From these secondary branches a third series appears, and these flowers are well filled with anthers that are abundantly polleniferous. The female organs of these flowers of the third class are, however, defective, as only a few bear capsules, and in these, a large portion of the seeds have no ovules. The polygamous character is confined to this third series of flower, the first two having purely pistillate blossoms. In these there do not seem to be the rudiments of stamens. The most remarkable part of this process of development is, that the whole of this first series of female flowers should open so long before the male ones come, that they fall unfertilised. The greater part of the second series also fall, and the crop of seeds is mainly made up of a few of the last opening ones of the series, and the comparatively few hermaphrodite ones which are found in those of the third class. It is a matter for curious speculation what special benefit it can be to the plant to spend so much force on the production of female flowers too early to mature, and then producing such an immense mass of pollen to go utterly to waste. Examining the flowers of the allied European evergreen ivy, *Hedera Helix* L., I find similar laws of distribution of the sexes as in *Aralia spinosa*, with the addition of a somewhat different structure in the male from the female flowers. In Europe the plant is described as often having a single umbel as a flower spike. It is quite likely in these cases that the flowers are hermaphrodite. In all the cases I have met with here, the inflorescence is a compound of several umbels — a terminal one female, and the lateral ones male, as in *Aralia*. But there are rudiments of stamens in the flower, and in occasional instances I find a filament developed; but never, so far, with any polleniferous anthers. The flowers of the central female umbel have rather longer and stronger pedicels than the lateral male ones. The calyx is united with the ovarium for one-half its length, and the latter much developed in the unopened flower. In the male the segments of the calyx are two-thirds free, and the petals are much longer than in the female flowers. As in *Aralia spinosa*, the male flowers do not open until some time after the female ones; and not before some of the latter, impatient of delay, have fallen unfertilised. I have so often and in so many varied ways demonstrated to the Academy that in plants the male element is a later and inferior creation, that it seems almost supererogatory to point out that these plants illustrate the same principle.

October 4.—Prof. Leidy made the following communications in palæontology. He directed attention to a collection of fossils from Sweet Water River, Wyoming Territory, recently received as part of the results of the geological exploration of Prof. Hayden. The most numerous and characteristic remains are those of a species of *Merycochœrus*, about two-thirds the size of *M. proprius*, from the head-waters of the Niolorara river. The species was named *M. rusticus*. Other remains found in association with the former are referable to a species of *Hipparion*, to *Canis vafer* and *Merycodus necatus*. Two additional fossils, from a tertiary deposit near Fort Bridger, are referable to a small species of *Lophiodon*, which was named *L. modestus*, and a small suilline pachyderm, which was named *Hyopsodus paulus*.

October 18.—Prof. Leidy directed attention to a collection of fossils received from the Smithsonian Institution, from Rev. Thomas Condon, of Dalles City, Oregon. The specimens were obtained from a tertiary deposit in the valley of Bridge Creek, a tributary of John Day's River, Oregon. The greater number and more striking remains belong to a species of *Oreodon* larger than any previously discovered. The skull is about fourteen inches in length, and is intermediate in character to that of *O. major* and *Merycochœrus proprius*. The species was named *Oreodon superbus*. Among other remains of the collection are those of *Oreodon Culbertsoni*, *Agriochœrus antiquus*, *Leptomeryx Evansi*, and *Anchitherium Bairdi*. A fragment of an upper jaw with two true molars probably belongs to *Lophiodon occidentalis*. Other fossils indicate ten species of *Rhinoceros*, probably *R. occidentalis* and *R. hesperius*. Others probably indicate *Elotherium superbum* and *E. ingens*. A small fragment of an upper aw with a molar tooth apparently indicates a larger species than *Anchitherium Bairdi*, and was referred to a species with the ame of *A. Condoni*.

October 25.—Prof. Leidy stated that he had recently received several boxes of fossils collected during Prof. Hayden's expedition in Wyoming Territory. Among the mammalian remains are those of a pachyderm about the size of an ox, and related to the *Chalicotherium* and *Titanotherium*. These were referred to a species with the name of *Palæosyops paludosus*. A fragment of a lower jaw, with true molars like those of the peccary, but with pointed lobes, was referred to a species with the name of *Microsus cuspidatus*. The animal was about the size of a rabbit. The remains of a lower jaw of an ursine animal, about the size of a raccoon, was referred to a species with the name of *Notharctus tenebrosus*.

November 1.—Prof. Leidy exhibited the tooth of a mosasauroid reptile from the miocene tertiary deposit of Gay Head, Martha's Vineyard. From the peculiar minutely-lettered appearance of the enamel, the tooth was referred to a species with the name of *Graphiodon vinearius*. He also referred to a now extinct species of crocodile, indicated by portions of a skull collected in Prof. Hayden's expedition, from a tertiary deposit of Big Sandy River, Wyoming. The skull, when perfect, measured eighteen inches long. It has nearly the form of that of *Crocodilus vulgaris*. The upper jaw is deeply indented back of the fourth tooth, and a pair of deep pits occupy the front of the palate. The species was named *Crocodilus Elliotti*.

PROGRESS OF SCIENCE IN 1870

THE year which has just come to a close has neither been characterised by many new and striking scientific discoveries, nor have any novel applications of Science to ordinary industry and manufacture attracted special attention. The work done has been more a strengthening of that of past years, and a confirming or a disproving of theories and experiments, than the inventing of new ones. In one branch of Science only has any great advance been made, and that, as we shall presently show, we believe to have taken place in Geology. But this advance is one somewhat overlooked at present; but still of so important a character that, when once fully recognised in all its bearings, it may tend to disprove much of the geological teaching of the present day.

Taking the various Sciences as much as possible separately, we will begin with ASTRONOMY. Here attention has been chiefly directed, as has been the case for so many years past, to the Sun. Since it is now generally understood that when once the nature of this vast self-luminous body is accurately made out, much light will be thrown on many now perplexing and strange phenomena, the Eclipse of the 22nd of December last was anxiously watched for, and all possible observations were taken here by those who were unable to take part in the Government Expedition to Spain and Sicily. It is to be hoped that the labours of this Expedition, in spite of accident both on land and sea, and the unsatisfactory state of the weather at the time of observation, will yet yield results of great importance. At any rate we may fairly congratulate ourselves that at last we have a Government which has shown itself in other instances besides this special one, not unmindful of the claims of Science and of the value of accurate scientific investigation.

Mr. Lockyer and Mr. Huggins have continued their spectroscopic observations of the Sun, and Prof. Zöllner has published a very valuable paper on the solar prominences, theorising very boldly as to the temperature and pressure at the Sun's surface;* while in America Prof. Young has worked with good results at the same subject. Before leaving this branch of our subject, we would mention that Mr. Proctor has published some novel views as to the constitution of the stellar systems, which, under the somewhat fanciful titles of "star-drift" and "star-mist" must be familiar to most of our readers.

Whilst the vast domain of ORGANIC CHEMISTRY has been still further widened by the innumerable workers who plunge into this branch of the subject and neglect the many untrodden paths in Inorganic Chemistry, nevertheless no special or important discoveries are to be chronicled, unless we may mention the beautiful process by which Indigo has been synthetically constructed by M.M. Emmerling and Engler, following closely on the artificial manufacture of Alizarine by M.M. Liebermann and Graebe.

MOLECULAR PHYSICS has occupied a large share of attention, and the discussion before the Chemical Society on the existence, or non-existence, of Atoms and Molecules, has only too clearly shown how doctors differ amongst themselves, and that the very foundations of a Science, considered so essential by some, are utterly repudiated by others. A very remarkable paper on the Size of Atoms, originally published in these columns (NATURE, vol i. p. 551) by Sir William Thomson, in which he gives four distinct trains of reasoning by which he arrives at a proof of their absolute magnitude, has attracted much attention, and has been translated and copied into most of the continental and American scientific journals. Dr. Thomas Andrews has also pursued his remarkable investigations on the Continuity of the liquid and gaseous states of matter. The death of Prof. Wm. Allen Miller, F.R.S., and Dr. Matthiessen, F.R.S., have left sad voids in the ranks of our English experimental chemists.

In BIOLOGY, the investigations of Prof. Tyndall, "On Atmospheric Germs, and the Germ Theory of Disease," * have contributed to a clearer knowledge of the nature of some of the most virulent of our infectious diseases, and have caused those diseases to be studied in a much more scientific manner than before.

The theory of Spontaneous Generation, which has been very prominently before the scientific world for the last ten years, has, during the past year, been very strongly attacked on the one hand by Prof. Huxley, and defended on the other by Dr. Bastian and Dr. Child. In his Inaugural Address to the British Association meeting at Liverpool, Prof. Huxley gave a long review of all the researches on the subject, from the time of Spallanzani and Needham to the present day, and declared his belief, after carefully weighing the evidence on both sides, that all life has its origin in some pre-existing life, and that Spontaneous Generation, or, as he termed it, Abiogenesis, is not now proved to take place. The investigations of Dr. Bastian, originally intended to have been read before the Royal Society, were published instead in these columns, in a series of three long articles (NATURE, vol. ii. pp. 170, 193, 219), in which he gave the reasons for his belief that Spontaneous Generation certainly does occur. Feeling himself attacked and his experiments somewhat underrated by Prof. Huxley in his Address, he criticised it at considerable length, and detailed the results of some new experiments (NATURE, vol. ii. pp. 410, 431, and 492) which confirmed his previous deductions.

The Darwinian theory of Natural Selection has been attacked by Mr. A. W. Bennett and Mr. Murray,† and defended by Mr. A. R. Wallace and others; Mr. Wallace having also vindicated his claims to priority in this question, since he published many of the now-recognised theories and speculations on the subject of Natural Selection, at a time when he was resident in the East Indies, and entirely unacquainted with what Mr. Darwin had written on the same subject.

As respects GEOLOGY, during the past year the Government has continued its grants of money for the purpose of Deep Sea Dredgings, and at present the report of the most recent Expedition is anxiously looked forward to. The results of the Expedition in the autumn of 1869, as given to the public by Dr. Carpenter, Prof. Wyville Thomson, and Mr. Gwyn Jeffreys during the past year, have been of the greatest possible interest and importance. They found that on the same level, at the

* See NATURE, vol. i. pp. 327, 351, 499, &c.
† NATURE, Vol iii. pp. 30, 49, 65, and 154.

bottom of the deep sea, two different deposits are in process of formation side by side, each characterised by a distinct Fauna, and yet apparently produced under perfectly similar conditions of land and sea, area, depth of water, &c. On investigating this curious result, however, it was found that the temperature of the water circulating over these two areas is very different, and that this mere difference of temperature is capable of entirely changing the character of the fauna of the simultaneously formed deposits. Thus an entirely new element is brought into geological speculations, since it is shown that at one and the same time strata may be accumulated containing widely different organic remains. In addition to this, they have shown that the calcareous deposit known to us as chalk is now being deposited all over the bed of the Atlantic Ocean, and there are many weighty reasons for believing that this deposit has gone on steadily ever since the time during which we imagined the cretaceous rocks of the world to have begun and ended. Many organisms formerly supposed entirely extinct have been re-discovered in these deep-sea dredgings; and, in short, much has been done to show that our past geological reasoning requires thorough and careful revision. Prof. Gümbel's discovery of the existence of Bathybius and similar organisms at all depths, and stretching over an indefinite period of geological time, is of the greatest importance in relation to this subject. Prof. Agassiz, on the other side of the Atlantic, has published reports of the deep-sea dredging off the Florida Coast, and has stated that the results of his researches, and those of others, both English and Scandinavian, have convinced him that there is life all over the sea bottom, and that where evidence of marine life cannot be found, we are justified in calling in the agency of the sea to explain certain obscure facts. These conclusions cannot be without their important bearing on many commonly received geological theories.*

In BOTANY many very careful series of observations have been made in the physiological department. Among the most important we may mention those of Prillieux and Duchartre in France, confirmed by Dr. M'Nab in this country, that, contrary to the previously accepted hypothesis, plants do not absorb any appreciable amount of aqueous vapour through their leaves; and those previously announced by M. Dehérain, that the evaporation of water from the leaves of plants is due to sunlight rather than to heat, and proceeds independently of the degree of saturation of the atmosphere. Much attention has also been paid in Germany, Italy, and England, to the fertile field of the phenomena of fertilisation, opened out by Mr. Darwin's observations.

In METEOROLOGY there is no great advance to chronicle. It still remains a Science without a head, a chaotic mass of facts with no definite order or arrangement; for though many are working at this subject, and some valuable papers on the Origin of Winds and Storms have been published, still no definite progress can be ascertained.

The splendid appearances of the Aurora Borealis, visible all over the British Isles in September and October, have directed public attention to those unmistakeably magnetic phenomena, and to the connection which exists between their appearance, great magnetical perturbations, and large solar spots. They have been examined very frequently during the past year by means of the spectroscope, and there is distinct evidence of lines in the green and red portion of the spectrum, the latter presumably due to hydrogen. We would direct attention to our desire to publish a complete tabular list of the more remarkable meteorological phenomena of the past year, so as to be serviceable to observers in all parts of the world. To render this as perfect as possible, we would invite the kind co-operation of all those interested in the subject who can forward us any data.

We cannot conclude without noticing how much Science has lost during the latter half of the year just ended by the fearful struggle that has taken place between France and Germany, where each nation has brought into requisition all the resources of Science only to inflict as much injury as possible on the other. For nearly six months we have witnessed the sad sight of workshops shut up, laboratories closed, universities and public schools wanting both professors and students, and the friendly emulation of similar tastes and pursuits turned to the fierce rivalry of the sword. Science will have to deplore the untimely loss of many of her most attached workers, and their country will have lost those who would in happier times have done her as much honour at home as they have shown bravery in the field. Whilst the French Academy, shut up in besieged Paris, has brought the art of ballooning to its present state of perfection, so that now it is used as a means of communication with the outside world, the result of the subtle strategy of the Germans, and the scientific education they so generally possess, has been to give them advantages which have, to the present time, baffled their adversaries. J. P. E.

* During the past year all the most important papers on Deep-Sea Dredging have appeared in these columns, and we would refer our readers to Vol. i. pp. 135, 166, 267, 612, 657; Vol. ii. pp. 257, 513 &c.

THE INTELLIGENCE AND PERFECTIBILITY OF ANIMALS

The Intelligence and Perfectibility of Animals from a Philosophic Point of View. With a few Letters on Man. By Charles Georges Leroy, partly under the pseudonym of "The Naturalist of Nuremberg." (London: Chapman and Hall, 1870.)

THESE Essays, written nearly a century ago, seem to have been intended chiefly as an answer to the doctrines of those French philosophers who maintained that animals were merely animated machines, or, as it was expressed by Buffon, that "the animal is a purely material being, which neither thinks nor reflects, but which nevertheless acts," and that "the determining principle of the animal's actions proceeds from a purely mechanical influence, absolutely dependent upon its organisation." Our author, on the contrary, maintains that the mental faculties of animals are strictly comparable with those of man; that they remember, combine, and reflect; that they are capable of self-improvement; and even that they possess a true language fully adapted to their needs. To support his views he gives what we may term a generalised life history of several animals, such as the wolf, fox, stag, fallow-deer, and roebuck, which his position of Ranger of Versailles and Marly gave him ample opportunities of studying. The chief fault of these interesting sketches is, that they detail hardly any of the special observation on which the generalised statements are founded. We are, therefore, unable to tell how much is fact and how much inference; and, what is probably the result of careful life-long observation fails to produce that effect of reality which a more direct narrative style would have given to it. In a few cases, however, he gives us actual observations; as when he proves that animals can count, by stating the fact that in order to destroy crows, which were destructive to game, a hut was made at the foot of a tree where there was a nest, in order to shoot the old birds when they returned to their young. It was found, however, that after the first time the man was always watched into the hut, and the crows would not return till he had left it or till night. To deceive them two men went to the door of the watch-house, one entering and the other passing on, but the crows would not come. The next day three went and two passed on, but still with no effect; and it was not till five or six went and all but one passed on, that they were deceived, being unable to count so many.

M. Leroy appears to reject altogether what is commonly termed Instinct, maintaining that the word should be applied only to those acts which are the direct consequences of organisation, such as the grazing of the stag, or the flesh-eating of the fox; but not to the expedients to which those animals resort in the gratification of their natural wants, which are due to sensation, observation, memory, and experience. To the objection that many animals perform complex operations perfectly well without experience, and always in the same manner, he replies that in many cases the fact is not so. He maintains, for instance, that there is a distinctly perceptible inferiority in the nests made by young birds, thus anticipating the observation of the American Wilson; and further remarks that the best constructed nests are formed by birds whose young remain a long time in them, and thus have more opportunity of seeing how they are made He says that the nests of young birds are ill-made and badly situated; and that the defects of these first constructions are remedied in time, when their builders have been instructed by their sense of the inconveniences they have endured. He maintains that nests of the same species of bird differ as much as human dwellings, and that of a hundred swallows' nests no two are exactly alike; and he imputes to want of long-continued observation our failure to discover improvement in them; a want which curiously enough, has been remedied by M. Pouchet, who has found a decided improvement in the nests of swallows at Rouen during his own lifetime. Our author has also some excellent remarks on hereditary habit, as strikingly shown in the case of many of our sporting dogs, and which, he believes, in wild animals is often mistaken for instinct; and he concludes that "It is possible that the actions which we see performed by some animals, independently of the teachings of experience, are the fruit of a knowledge of very ancient date, and that in former times a thousand trials, attended with more or less success, have finally led to the attainment of the degree of perfection which we see manifested in some of their works at the present day."

The migrations of birds, also, he maintains are the result of no blind instinct, but of instruction handed down from generation to generation. He says, "Let us take the swallows as an example which every one can observe. In the first place, their departure is always preceded by assemblages, the frequency and duration of which can leave no doubt that their object is to effect all the necessary preparations for a voyage undertaken by creatures who have the faculty of sensibility, and of understanding one another, and who are united for a common purpose. The incessant and varied twittering which reigns in these assemblies, clearly indicates communications and orders, indispensable for the numerous offspring of the year. They must stand in need of preliminary instruction, constantly repeated, to prepare them for the great event. Frequent trials of flight are no less indispensable, and are often followed by a repetition of previous lessons, which makes our roofs and chimneys ring again. Assemblies of men who should speak a foreign language could not give more evident signs of a similar project. But there is a more convincing proof than this analogy that these migrations are not the result of a blind and mechanical inclination. When, at the time fixed upon for the flight, which cannot, owing to weather, be retarded without compromising the welfare of the whole species, some, and even a large number of indviduals, are too young to follow the rest, they are left behind and remain in the country. But it is in vain that they reach maturity; the supposed *attraction towards a certain region* dees not affect them, or too slightly to enable them to gratify it. They perish, the victims of their ignorance, and of the tardy birth which made them unable to follow their parents."

The letters on Man, which are curiously mixed up with those on animals, are neither so interesting nor so well reasoned. Their object is mainly to deduce the complex phenomena of human existence from the two principles of "the love of ease" and "*ennui*," which being antagonistic, lead men to all kinds of expedients to secure the one or escape from the other. These, with sympathy, which he considers the pre-eminently human emotion, are made to explain most of the facts of man's mental nature. The work is written throughout in a pleasing and simple style, and exhibits to us a loving student of nature who observed and thought for himself, and who, in many of his conceptions, was far in advance of the great philosophers of the last century, among whom he lived.

ALFRED R. WALLACE

OUR BOOK SHELF

Use and Limit of the Imagination in Science. By Prof. Tyndall. (London: Longmans and Co.)

THIS is a second edition of Dr. Tyndall's Discourse at the meeting of the British Association at Liverpool. To it is now appended his Address as president of Section A of the British Association at the Norwich meeting. This was analysed by Dr. Clark Maxwell at a later meeting (see NATURE, Liverpool Meeting, Address to Section A). There is also added a short Essay from the *Saturday Review*, with the quaint title of "Earlier Thoughts," suggesting the irrepressible "Country Parson," A.K.H.B. Another curious addition is a selection of favourable, unfavourable, and often ridiculous critiques of various parts of his discourse; which reveal the existence of a strange state of things in the arcana of editorial dens.

One or two trenchant notes are appended to the Discourse. That regarding "microscopists" and spontaneous germ-formation is especially deserved and well laid on. This race of pseudo-experimenters, who do not know the simplest necessities of accurate experiment, but who by mere assertion endeavour to bear down genuine scientific men, is really the class which does mischief alike to science and to the cause of religion. Dr. Tyndall is certainly not fairly censured by the so-called "religious" press, but does it ever deal either praise or censure fairly? His remarks on the Materialists at the end of the Address are quite conclusive as to the absurdity and injustice of calling him by that name. There is a verse in Scripture that would suit the case exactly, but we leave the problem as a puzzle to the Editor of the *Record*.

The Student's Manual of Comparative Anatomy and Guide to Dissection. By G. Herbert Morrell, M.A., B.C L. (Oxford: Shrimpton.)

WE have received the only part as yet published of this treatise, viz., that relating to the Birds. Mr. Morrell gives with great care, in a tabular form when possible, a condensation of all the information to be obtained in such works as Huxley's "Lectures on the Skull," and "Classification of Birds," Wagner's, Siebold's and other manuals, and the "Cyclopædia of Anatomy and Physiology," supplementing this by extracts from his own notes of dissections in the anatomical laboratories of the Oxford University Museum, and of Professor Rolleston's lectures given there. It is proposed to issue an atlas of woodcuts borrowed from various works to illustrate the letterpress. The book will be found very convenient by students at Oxford and elsewhere, who are carefully studying the comparative anatomy of the Vertebrata. We must decidedly object, however, to the omission of one group of organs *entirely* —the reproductive. It is a concession to a strange prejudice, and really renders a good work incomplete.

E. R. L.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

The Eclipse Expedition

I WRITE you a brief account of the doings of the English Eclipse Expedition up to the present time, thinking it may be interesting to your readers.

After leaving London we proceeded direct to Naples, staying on the road only a few hours at Cologne, half a day at Verona, and a day at Rome. Everywhere on the journey the most marked kindness was shown to the Expedition as the representatives of English Science. From Ostend to Verona we never changed carriages, and there only on account of a slight breakage in the carriage itself. Never once were we asked for passports, never once were our instrument cases overhauled, or anything beyond mere personal baggage, at the custom houses. At Naples we stayed a day, which was occupied in taking the lids off all the cases, repairing one or two slight accidents which had befallen the instruments, and making plans for our distribution in Sicily.

At four o'clock in the afternoon of Wednesday, the 13th, we were all on board the *Psyche*, a despatch boat which had been lent by the Government to convey ourselves and instruments to Sicily. A delicious sunny afternooon, a sea as smooth as molten glass, a ship's company receiving us with the utmost kindness and hospitality, how could the evening not pass as merry as a marriage bell? I cannot retail to you all the jokes which passed, the lively chats and quiet strolls by moonlight, the polariscopes and spectroscopes pointed to the sea and sky, ere long destined to address their momentous questions to the Sun himself, now having their merits and demerits freely discussed by the *savants;* but you can imagine it all. At last we turned in to enjoy that repose which sea air always induces in landsmen.

At about six we were all called and told we were approaching the Straits of Messina, the very Scylla and Charybdis of our classical lore. In moonlight, soft, cool, and delicious, we beheld those rocks of Scylla and steered through Charybdis, though we felt it not, and so onwards in the rising sun through the Straits. After breakfast we held our (as we then thought) final council only about an hour before we were to separate for our various Sicilian stations. Scarcely had the council broken up, when the sad event occurred which was destined to alter all our plans. We were steaming along about ten miles north of Catania, the gigantic cone of Etna, capped with snow, appearing to rise from the cliffs of lava under which we were passing, when the ship struck on a treacherous sunken rock, shown in none of the charts. I cannot pass over this sad catastrophe without referring to the noble behaviour of our gallant commander, Lieut. Fellowes, to whose coolness and energy we owe the safe disposal of ourselves, instruments, and baggage at Catania, without any serious loss. Mr. Lockyer, at the request of the captain, immediately telegraphed to Malta, whence the *Royal Oak* came to the aid of the *Psyche*. More lately the admiral of the Mediterranean fleet (Sir Hastings Yelverton) has arrived in the *Lord Warden*, and anchored beside her, and I am glad to be able to say that if the present calm weather continues there is every prospect that the ship may be saved.

For this expedition it was found necessary to make Catania the head quarters instead of Syracuse, as had been originally intended, as there would inevitably have been too great delay in removing the heavier instruments to Syracuse to carry out the original plan. Since our arrival, we have received all possible help from our own and the Italian Governments. From the latter we obtained the use of the garden of the Benedictine monastery, where we are working, as well as guards at some of our stations. Both here and elsewhere the American and Italian observers join heartily with us, and to their co-operation we owe much.

The arrangement of the English parties are now as follows. At Catania we are strong in the spectroscope. Mr. Lockyer and Mrs. Lockyer are working with a large reflecting mirror fitted with a single prism, but with special adaptation for giving plentiful illumination, as well as for placing the hydrogen spectrum side by side with the spectrum obtained from the corona. Mr. Seabrokes has a large refractor fitted with a spectroscope of six prisms for examining the chromosphere. Mr. Pedler works with a small direct-vision instrument. Prof. Thorpe has mounted his apparatus on the top of a portico in the garden, and has been engaged the last few days in making out daily curves of the chemical intensity. To Mr. Vignolles, sen., and Mr. Vignolles, jun., and myself are committed the time and general observations. In addition to the above, we hope to have the assistance of several of the officers from ships in the neighbourhood, who will make sketches of the appearances, and help the observers in various ways.

Our next detachment, under the charge of Prof. Roscoe, has left us, intending to find a stage of observation as high as possible on Etna. It is confidently expected that, by leaving some seven or eight thousand feet of the densest atmosphere behind, delicate but important observations may be made which would be impossible at a lower level. This party is piloted by Prof. Sylvestre, of the University of Catania, who, in common with all the authorities here, has shown the utmost courtesy toward the Expedition. The spectroscope observations will be conducted by Prof. Roscoe, with the assistance of Mr. Bowen; the polariscope is under the charge of Mr. Harris; photographic arrangements under Dr. Vogel; while Mr. Darwin will sketch the appearances presented.

At Agosta we are strongest in the polariscope, this instrument requiring the longest possible duration of totality. The party is under the charge of Prof. Adams (of King's College, London), who, in the polariscope, is assisted by Messrs. Ranyard and Clifford. The only spectrocopist stationed here is Mr. Burton, and the sketcher, Mr. Brett. This party have been living under canvas for the last few days, and, I need hardly add, received the utmost kindness from a military detachment stationed there with them.

At Syracuse we are only represented by one photographer, Mr. Brothers, assisted by Mr. Fryer and by Mr. Griffith, who will take observations with his polarimeter.

The authorities at Malta sent us here two sappers, thanks to whose exertions our observations have been erected with great rapidity, enabling us to station our instruments and make preliminary trials in the very positions they will occupy during the Eclipse. Since our arrival these preliminaries have kept us all extremely busy, and the ultimate success of our operations must in a great measure be attributed to the unremitting energy of Mr. Lockyer and Prof. Roscoe.

Up till to-day the weather has been superb, day after day just like the warm days we often have in England towards the end of June. The thermometer in the shade has reached from 75° to 80° F., while the barometer has been steady, but with just sufficient tendency downward, to fill with gloomy apprehension the less sanguine of our party. During this afternoon things do not look well, heavy clouds have been sailing over head, and have quite shrouded the upper five thousand feet of Etna; but we have yet hope, and all we can do is to wait patiently for about twenty hours, hoping then to get at least a bright gleam for the space of a minute and a half. If the sky so far favour us doubtless to-morrow will be an epoch in the history of astronomy.

L. CUMMING

Catania, Sicily, Dec. 21, 1870

The Eclipse

A REMARKABLE phase in the moon's passage across the sun was the perfect apparent contact of the limb of the moon with a sun-spot, of which the annexed figure is a fair representation. The noticeable thing was that the body of the moon itself and the sun spots were of so precisely the same tint that no trace of a division was perceptible, one appearing to be merged in the other as long as the contact lasted.

Exeter, December 22, 1870 W. F.

Eozoön Canadense

THE letter of Mr. T. Mellard Reade on the subject of *Eozoön Canadense*, contained in your number for December 22, exhibits so complete a misapprehension of the state of our knowledge of that fossil, that I feel it necessary to break the silence which I have for some time imposed upon myself as regards this subject, in order that your readers may not be misled by the positiveness of his assertions.

1. Mr. Reade speaks of Eozoön, with the exception of the Tudor specimen, as having been obtained *only from metamorphosed rocks*. In reply to this, I have to state that the Eozoönal structure is *most* characteristically displayed in those portions of the Serpentine Limestone of the Laurentian formation which have undergone the *least* metamorphic change. In fact, the Calcareous lamellæ of the best specimens of Eozoön in my possession show less departure from the shelly texture with which I have become familiarised by the special study of the microscopic appearances of Shell, &c., for more than thirty years, than do the great majority of undoubted shells, corals, &c., contained in the least altered rocks of any geological period.

2. Mr. Reade assumes that the presence of the Serpentine lamellæ, which alternate with the Calcareous lamellæ, is itself an indication of metamorphic action. This position can only be sustained by those who are ignorant of the processes which can be shown to be at present going on upon the sea-bottom, and of which we have evidence in various geological periods; whereby the sarcodic substance of animals of various types of organisation, but especially of *Foraminifera*, undergoes replacement by siliceous compounds precipitated from sea-water during its decomposition. It was long since shown by Prof. Ehrenberg, that green sands of various ages, from the Silurian to the Cretaceous, are essentially formed of the *internal casts* of Foraminifera. The late Prof. Bailey (U.S.) first proved that the production of such internal casts is taking place at the present time. I have long had in my possession a set of beautiful internal casts of this kind, procured from the late Mr. J. Beete Jukes's dredgings on the coast of Australia. And quite recently I have obtained from Captain Spratt's dredgings in the Ægean a most remarkable series of such casts, which includes representations in green and ochreous Silicates, not merely of the sarcode-bodies of *Foraminifera*, but also of the sarcodic network that occupies the interspaces of the calcareous reticulation which I demonstrated twenty-three years ago (Brit. Assoc. Report for 1847) to be the basis of the skeleton throughout the class of *Echinodermata*. And Dr. Duncan has shown that a like process is taking place at the present time in the case of *Corals*; their animal substance being replaced by Silicates, whilst their Calcareous skeleton remains unchanged. No *mechanical* agency can account for this replacement. It is not effected by the percolation of Silicates in solution, under the "*hydrothermal*" action which Mr. Reade (following the lead of Messrs. King and Rowney) invokes as having been concerned in the production of the Canadian Eozoön. And I am justified by the opinion of several of our ablest Chemists and Mineralogists in the assertion that no agency save a progressive *chemical substitution* can account for the production of these wonderful models; the Silicates being precipitated from sea-water by the decomposition of the sarcodic substance which they replace and represent. Whether or not this doctrine be accepted, it may be confidently affirmed that whatever be the agency concerned in *their* production, the filling-up of the cavities of the Calcareous skeleton of Eozoön may be fairly accounted for in the same manner.

3. The most characteristic features of the best-preserved specimens of the Canadian Eozoön can thus be completely paralleled by those of analogous formations at present going on. Let us suppose that the North Atlantic sea-bed, instead of being covered by minute individualised *Globigerinæ*, were occupied by a shell-producing Rhizopod having the indefinite extension of *Bathybius*, and that its sarcodic substance came to be replaced (as in the instances just cited) by Silicates precipitated from sea-water; such a composite formation, elevated so as to become a terrestrial rock, *without any metamorphism whatever*, would be the precise parallel of the *Eozoön Canadense*. And just as, at the present time, the replacing minerals are not always the same, though always compounds of Silica, so the substituted material in Eozoön often consists of other minerals than Serpentine, always, however, being Silicates. In fact it was the *uniformity* of Morphological character, with *variety* of Mineral composition, that first led Sir William Logan—a geologist second to none in experience and judgment—to the suspicion of its organic origin.

4. Mr. Reade represents me as having made "the important admission" that "the several features in the structure of Eozoön (chamber-casts, canal-system, and proper walls) could be separately paralleled elsewhere," meaning, I presume, in undoubtedly Mineral structures. I have nowhere, that I can recollect, made any such admission: on the contrary, I have repeatedly argued that whilst the *combination* of structural characters in Eozoön affords the most unmistakeable evidence to those whose previously acquired knowledge enables them to appreciate their value, there are individual features which are inconsistent with any conceivable hypothesis of its purely Mineral character. Of these I may here state two, which I have always found to be most convincing to such as are familiar with the microscopic appearances of Minerals: *First*, the fact that the "canal-system" which traverses the Calcareous lamellæ passes *across* their cleavage-planes, instead of *between* them; and that this canal-system has precisely the same distribution, whatever may be the mineral which occupies its tubes, whilst its finest ramifications are frequently filled with calcite, as in the least-altered fossil Foraminifera. The idea that such arborescent expansions can have been produced by any kind of *infiltration* of one mineral into another, is thus, in the judgment of some of the most eminent Mineralogists of the day, *altogether untenable*; whilst the *precise parallelism* pointed out by Dr. Dawson, between the canal-system of Eozoön and that which I had shown to exist in the recent *Calcarina*, is no less satisfactory to Naturalists conversant with Foraminiferal structure. *Second*, the fact that the "Nummuline layer" or "proper wall" of the chambers consists of a Calcareous lamella traversed by Siliceous aciculi, which sometimes lie straight and parallel, are sometimes curved, and sometimes penicillate; the precise equivalent to this being shown in the chamber-walls of recent Foraminifera, when the pseudopodia which occupied their tubuli during life have been replaced by Silicates. I assert again, on the authority of Mineralogists of the highest eminence, that such an arrangement cannot be shown in any undoubted mineral, and that it cannot be attributed to any physical agency. To liken this "Nummuline layer" to Chrysotile or any similar modification of Serpentine, shows a misapprehension of its essentially composite structure.

5. I cannot admit that the question of the Organic nature of the Canadian Eozoön (if question it be) is in the least degree affected by the occurrence of Metamorphic rocks presenting more or less morphological resemblance to it, in combination with undoubtedly Mineral characters. We should never think of deci-

ding the nature of Chalk, or of any more ancient Foraminiferal limestone, by the condition of its altered forms; the evidence of their Organic origin being supplied by the microscopic examination of specimens exhibiting the least evidence of change, and this evidence being not in any degree invalidated by the most complete mineralisation of particular examples. A large number of specimens of Ophicalcite have been submitted to me from various sources, as to some of which I have been able to say pretty confidently that they were originally Eozoic, but have been altered by subsequent metamorphism; whilst others do not present any feature whatever which would lead me to assign to them an Eozoic origin. To assume that these last (of which the Strath rock may be an example) are to be placed in the same category with the Canadian Eozoön, and thence to affirm that because they are purely Mineral productions, *it* cannot be Organic, involves a *petitio principii* by which it would be perfectly easy to prove the same thing of Chalk.—Let me illustrate my position by a parallel case. I have lately demonstrated* the existence of a Foraminiferal structure *departing much more widely than Eozoön does from any previously known type*, in a class of globular bodies from one to two and a half inches in diameter, occurring in the Upper Greensand; these having been previously regarded by experienced Geologists as mere Mineral concretions. Now, it so happens that the Magnesian Limestone of the North of England contains large masses of spherical concretionary bodies, bearing a strong *general* resemblance to *Parkeria* in internal structure as well as in outward form, but hitherto regarded, I believe universally, as Inorganic; and a reasoner like Mr. Reade would argue in this way:—"Because impartial geologists have pronounced the Permian concretions undoubtedly inorganic, the Greensand spheres are so likewise; and Dr. Carpenter's *Parkeria* becomes extinct as a fossil." But it likewise happens that the structural features which are most peculiar in *Parkeria* present themselves also in a remarkable living Foraminifer recently obtained from great depths in the *Porcupine* dredgings; so that the truly Foraminiferal nature of *Parkeria* cannot be a matter of the slightest doubt. And the only question now is, whether a careful microscopic examination of the minute structure of the Permian concretions may not afford, through its likeness to that of *Parkeria*, more or less definite indications of *their* Organic origin, obscured by subsequent metamorphism. The application is obvious.

6. I am equally unable to admit that if a rock presenting all the characteristic features of the Canadian Eozoön were to be found shading off into one containing characteristic Liassic fossils, this would afford the least tittle of evidence against the Organic character of the former. As the *Lingula* of the ancient Siluria has, in the judgment of our most eminent Brachiopodist, come down unchanged to the present time, and as even the same *varietal* modifications of Foraminiferal types were existing in the Triassic period as now in the Mediterranean, I see no reason why we should limit Eozoön to the Laurentian epoch. When this subject was last discussed at the Geological Society, I ventured to say that it would not in the least surprise me to find Eozoön, or something very like it, now existing on the deep-sea-bottom; and the notion was not treated by any of the eminent Geologists then present as having any *a priori* improbability. Since that time, the Coccoliths first discovered by Prof. Huxley, and the Coccospheres first observed by Dr. Wallich, in the Globigerina-mud, and afterwards recognised by Mr. Sorby in Chalk, have been detected by Prof. Gümbel in Silurian rocks; so that it is clear that the Biological condition of the deep sea has changed much less in vast periods of Geological time, than has that of shallower waters; whilst the probability has now almost reached a certainty that Rhizopodic life has been at least as largely concerned in the production of Calcareous deposits in earlier Geological periods, as we know it to have been in the later.

7. Though Mr. Reade "feels assured that whenever impartial Geologists take the question up, the fossil itself will become extinct," his assurance is not borne out by the judgment of the large number of impartial Zoolgists, Continental as well as British, who have satisfied themselves, by a careful examination of my series of microscopic preparations, of the Organic nature of the Canadian Eozoön, and have authorised me to express their entire accordance in my interpretation of its phenomena. An eminent Professor in one of our own Universities used this emphatic expression—"The matter seems to me not to admit of *hesitation*, much less of *doubt*." My last Continental visitor, Prof. Carus, who is well known to possess a comprehensive and practical knowledge alike of Zoology, Palæontology, and Mineralogy—assured me that having come without any prepossession on the subject, he left me with a full conviction of the justice of my views. The respect paid by such Naturalists as Professors Milne-Edwards, Carus, Lovén, Van Beneden, and Escher von der Linth,—typical representatives of the Science of France, Germany, Sweden, Belgium, and Switzerland,—to my own judgment in a matter as to which *they* regard the special studies of a third of a century as giving me some claim to authority, may console me for the contemptuous repudiation of microscopic evidence in which Mr. T. Mellard Reade has thought it becoming to indulge. I am far from expecting, however, that anyone should pin his faith upon my own *ipse dixit*, supported though it be by the entire concurrence of my three fellow labourers in Foraminiferal investigation, Messrs. Parker, Rupert Jones, and H. B. Brady. And if it be thought that the decision of any tribunal of really "impartial geologists" is likely to carry more weight with the scientific public than that of the authorities I have cited, I am perfectly willing to go into the question with them; provided, however, that such tribunal consists of, or at any rate includes, men who are sufficiently conversant with the Microscopic appearances of undoubtedly Organic structures, to be able to recognise such appearances when they see them. One of the strongest opponents of the Organic origin of Eozoön designated as "an agatized mineral" a section of a *recent* Nummuline shell, that exhibited a minute tubulation corresponding with that of the nummuline layer of Eozoön, which he had just before characterised in the same manner. Another attributed the production of a perfectly mineralised internal cast of *Polystomella* in green silicate, from Capt. Spratt's Ægean dredgings, to the working-in of mud. And a third has abstained from even looking at my specimens, though I have repeatedly expressed my willingness to give him an opportunity of examining them. Such are *not* the judges before whom I would consent to plead the cause of *Eozoön*.

WILLIAM B. CARPENTER

* See my description of *Parkeria* in the Phil. Trans. for 1869.

Mimicry *versus* Hybridisation

ALLOW me space for a word or two in reply to Mr. Wallace and Mr. Butler's observations on my papers on Mimicry and Hybridisation.

There is only one point in my argument to which they have taken exception, and although, of course, I am not therefore entitled to assume that their silence on other points means assent, I may at least infer that in their view the point objected to is most open to assault, and that if it were established, the reader may regard the rest with increased confidence.

The objection is that the instances of hybridisation in plants which I have cited as parallel to the cases of mimicry between the Danaids and Nymphalids were merely cases of hybridisation between species of the same genus or allied genera, whereas these butterflies are more distantly related. The question, as thus put by these gentlemen, resolves itself into a question of comparative degrees of affinity, and Mr. Wallace, with his usual skill, tries to throw the onus of proof from his shoulders to mine. But with all submission we shall keep it where it naturally lies. He puts it that my argument rests on the assumption that hybridisation can take place between different orders or families, and quite logically (supposing me to have done so) objects to my making any such assumption in regard to insects, seeing that nothing of the kind has ever been observed in other animals or in plants. But I rest my argument on no such assumption. I ask no other measure for insects than is given to plants. It is Mr. Wallace who makes the assumption that the amount of difference between Lepidoptera has a different value from that attached to it in any other organic beings. It is he who claims for differences which in any other creatures would be regarded as no more than specific the importance of generic or ordinal. But however this may suit the artificial classification of the systematist, we cannot allow it when we come to deal with the actual workings of nature.

I am not surprised that either Mr. Wallace or Mr. Butler should take what appears to me an exaggerated view of the dignity and position of their favourite group. It is human nature that any subject to the study of which we have devoted ourselves should assume in our eyes larger proportions than it does in the eyes of those who take a wider but less detailed view of it. Hence we see Mr. Butler comparing the Lepidoptera to birds, as if it were a kingdom of equal magnitude, and seeking for equivalents for such groups as the hawks and doves within its limits. Whereas it seems to me that the truer parallel is between the whole class Insecta and Birds, and that the equivalent groups for hawks, doves, &c., are to be looked for, not in one of the sections, but in the whole of the class. He looks for both hawks and doves in the *Lepidoptera*. I find nothing but doves. If you want hawks you must go to the dragon-flies, which are their equivalent; and, of course, if we are only dealing with doves, there is nothing in the known phenomena of hybridisation opposed to such a cross having taken place.

It is impossible in the brief space that you would allow me, even to glance at the many arguments that I could adduce to show that this is the true position of the *Lepidoptera*. I hope to do so elsewhere. But I would only remind entomologists, especially lepidopterists, of the trifling characters on which their genera have been established, and how difficult it has been to find any generic characters at all. This is frankly acknowledged as the great difficulty attending the study of *Lepidoptera*, consequently characters which would never for a moment be looked on as generic in any other group of animals, are there allowed that value. If any specialist in another group objects, what is the answer? "We have no better characters, and we must do the best we can with the slight ones we possess." Quite right, in a systematic point of view. If the species of doves came to be reckoned by thousands, the ornithologist would just have to do the same thing; but that would not alter the position of doves in the animal kingdom—they would still bear the same relation that they do now to hawks, and be equally open to hybridisation among themselves, indeed, more so; for such great numbers of one type would be a presumption in favour of every mode by which species could be increased having been resorted to; and this by the way is an additional indirect argument in favour of hybridisation sometimes taking place among *Lepidoptera*.

Of course, I do not mean to say that there is nothing more than specific distinction between the Danaids and Nymphalids. I recognise them as good genera, but only as genera sufficiently nearly akin to allow of hybridisation taking place between them—and *ecce signum*—the mimics in question partaking of the characters of each in all respects as other hybrids do.

ANDREW MURRAY

67, Bedford Gardens, Kensington, Dec. 30, 1870

Measurement of Mass

THE favourite definition of *mass* in the text-books seems to be that the mass of a body is the *quantity of matter* it contains. If we had to do with but one kind of matter this would be intelligible, but I am at a loss to know what is meant when it is said that a piece of cork contains as much matter as a piece of lead. The only satisfactory method of explaining what is meant by the mass of a body, is to define it as a constant belonging to the body, which expresses the proportion between the force (measured statically) acting upon it and the acceleration produced; that every body has such a constant is the result of experiment. The mass of a body has no necessary connection with its weight. We employ weight to measure mass simply because gravity is a convenient constant force. If then we adopt a pound as our unit of *weight*, and use g to denote the force of gravity in reference to a foot and a second as the units of length and time, our unit of mass becomes the mass of g pounds, and this is not variable, although the unit of weight employed is variable; since if a true pound, as determined at London, were carried to the North Pole, it would weigh more than a pound, precisely in the proportion in which gravity at the Pole is greater than gravity at London.

THE REVIEWER OF EVERETT'S "DESCHANEL"

PHOTOGRAPHIC PROCESSES OF THE PRESENT DAY

THE last two or three years will certainly mark an era in Photography, for not only have several novel and important printing methods been discovered during that period, but other processes of less recent origin have of late been so elaborated and improved as to have become at the present moment practical and easy of manipulation. All of these are, without exception, based upon the action of light upon the bichromates of potash and ammonia; in no single case is the use of a silver salt involved—the agent employed for securing the photographic image in ordinary paper printing—and this is, in truth, a point whose value cannot be too greatly insisted on; for the silver print, be it washed and freed as thoroughly as possible from any deleterious bodies, will always suffer, more or less, from attacks of an impure atmosphere, the delicate metallic film of which the image consists being peculiarly liable to change, from the sulphur compounds and other impurities not unfrequently contained in the air we breathe. And even those silver pictures which do not at first show actual traces of fading or discoloration, will very soon be found, on careful examination, to have parted with some of their original brilliancy, and to lack the pristine freshness which always characterises newly-produced albumenised prints.

It is a great step onwards, then, to have at our disposal practical processes in which the employment of silver may be altogether dispensed with, by the substitution of another material of a more permanent character, either in the form of a chromium compound, or, what is better still, in the shape of gelatinous or greasy ink; and so clear and promising does the photographic horizon appear just now in this direction, as to leave little ground for doubting that before long the practice of printing in silver will be generally abandoned.

All recent printing processes rest, as we have before said, on the action of light upon the bichromates, and here we would parenthetically refer to a simple and familiar experiment which will help very materially to simplify our subsequent remarks. The well-known plan pursued by school-boys for printing fern-leaves and other objects by the aid of the sun, will readily be called to mind by many of us, and this simple manipulation it is that forms the groundwork of the whole series of inventions before us. A sheet of ordinary paper, which has of course been sized, or, in other words, received a thin coating of gelatine, is rubbed over with a solution of bichromate of potash; the latter, as we know, when mixed with any organic body renders the same sensitive to light, and the sizing or gelatine upon the paper becomes in this way endowed with excitable properties. Having been dried in the dark, our sheet of paper is next placed in the sun with the fern-leaf, or other object to be copied, pressed down upon it, and the light acting upon all such portions of the sheet as are not covered up, browns the gelatine there and renders it insoluble; the sizing underneath the leaf, and screened therefore from the light, escapes this reaction and remains soluble, and this, on the printing being completed and the paper washed in water, is at once dissolved away, there remaining a white image of the leaf upon a brown ground composed of bichromated gelatine rendered insoluble by the sun's rays. This experiment may be regarded as the key to the whole question of photographic printing, and by bearing it in mind the reader will have no difficulty in at once comprehending the various inventions of the kind just now being made public.

The first method claiming our attention is the so-called carbon process. Photographic printing of this nature in one form or another has been carried on probably for upwards of fifteen years; but in its experimental stage the mediocre character of the results furnished by it were such as to deprive the system of any material support from photographers, and until, in fact, Mr. J. W. Swan, of Newcastle, made known his method, no easy or reliable *modus operandi* can be said to have existed. The plan followed by Mr. Swan was to prepare a warm solution of gelatine and bichromate of potash mixed with some finely divided pigments, such, for instance, as Indian Ink, and apply this mixture in the form of a coating to a sheet of paper, so that when dry, the tissue, as it is called, assumed the form of a thin, black cake with a paper backing. This sensitive tissue was placed under a negative to print in the ordinary manner, the light penetrating in parts to a greater or less degree, and thereby rendering the surface partially insoluble. On removing the tissue from the printing frame, it might, if it were desired, be forthwith washed to remove the soluble portions (as in the case of the fern-leaf experiment), but by so doing the picture would be hard and deficient in detail, and therefore a slight modification is here instituted. Instead of washing away from the face of the tissue, the operation is pursued from the back, the film being in the first place cemented face downwards upon a sheet of india-rubber, and in this condition put into a tank of warm water. The original paper backing of the tissue is in this way at once washed off, as is also every part of the gelatine mixture not rendered insoluble, which latter, constituting the image itself, remains attached to the india-rubber sheet before mentioned. The picture is now sufficiently developed, and indeed quite perfect, except that it is reversed to our view, for we are looking at it, it must be remembered, from the back; this defect is, however, easily remedied by attaching to the image another sheet of paper by means of gum or gelatine, and then dissolving off the india-rubber facing by means of benzole or turpentine, when the finished image is obtained resting upon a support of white paper. The object of washing the carbon tissue from the reverse side and not from the front, or surface exposed to the sun, is to secure the finer details in the picture by fixing at once to a basis such portions of the tissue as may have been but very slightly acted upon, and thus prevent them from being ruthlessly washed away when placed in warm water.

The actual composition of pictures produced in this manner consists of gelatine, pigment, and a stable chromium compound, the gelatine being in a fixed or tanned condition, by a subsequent immersion of the prints in a solution of alum, and thus there is every reason to believe in the permanent character of such prints. A more simple and ready method of carbon printing has been lately invented by Mr. Johnson, and termed the Autotype process, but the principles involved therein are nearly the same.

Passing from printing in permanent pigments, in which, as in silver printing, the aid of light is necessary for the production of each separate picture, we come next to photo-mechanical methods. Of these there may be said to be two kinds partaking of the nature of lithographic and engraving methods. Of the first description we may mention three modes of working, all of which are capable of yielding very creditable specimens of printing: these are Albert-type, the Lichtdrück process, and Edwards's collographic method. The three inventions, which differ from each other and from minor plans of a similar nature only in a few details, are all based on the same principles. A sheet of patent plate glass is in the first place coated with a thick solution of bichromate of potash and gelatine; this film on drying is placed face downwards upon a sheet of black paper in the sun, and in this way the light rays penetrate the glass and act upon the sensitive compounds adherent to its under side. The bichromated gelatine becomes insoluble and firmly cemented to the glass, except on the exterior surface, for the black paper upon which this has rested absorbs the rays and leaves the outer film of gelatine still in a soluble condition. A second coating of the sensitive gelatine mixture is now applied to the former one, to which it adheres perfectly, from the fact of the first surface being unchanged, and upon the second coating an image is printed by means of a negative in the ordinary manner. After printing, the progress of which, by-the-bye, may be watched through the glass, instead of washing the surface and dissolving out all the soluble parts, a sponge dipped in cold water is simply rubbed over it, the moisture being absorbed by the gelatine where it has not been acted upon by light, and is capable therefore of swelling out; those portions of the film, on the other hand, which have been rendered quite insoluble and hard, are unable to take up any water whatever, and remain untouched therefore by the action of the sponge, while other parts again, slightly exposed to light, absorb water just to that degree to which they have remained soluble. In this condition an inked roller is passed over the surface, in the same manner precisely as in lithography, the greasy ink adhering to all the insoluble surfaces (where no water is), and to the other parts in a greater or less degree according to the amount of water present in those places. Thus the gelatinised glass is treated in every sense like a lithographic stone, being moistened, inked, and pressed in the same manner; the resulting print, however, is generally finer than that obtained in ordinary lithography, as the graining of a stone surface is always somewhat coarse, while in the present instance the breaking up of the ink by the minute pores of the gelatine impregnated with moisture is of an exceedingly fine character. Many thousand prints may be pulled off a printing block of this kind before it is destroyed, as the double layer of gelatine imparts a yielding nature to the plate which is not easily damaged; in Germany, in England, and also, we believe, in America, this process of photographic printing is extensively practised.

But by far the most important of all methods yet discovered is the Woodbury engraving process. So simple, and at the same time so perfect in its work, a casual observer cannot but fail at once to appreciate its value. A thin sheet of gelatine is sensitised by impregnation with bichromate solution, and exposed to light under a negative; subsequent immersion in warm water removes the soluble portions from the surface, and we have then a thin gelatine plate upon which the image is represented, more or less, in relief. This matrix, as it is called, is hardened by treatment with alum, and placed when dry in a hydraulic press, in contact with a plate of type metal. Subjected to considerable pressure the metal plate takes the impression of the relief, and thus becomes in every sense an engraved plate, in which the darkest shadows are represented by the deepest hollows, the half-tones by slight undulations, while in the high lights there is no depression at all. The printing off of copies from this engraved plate is very ingeniously contrived. A little pool of transparent gelatinous ink is poured upon a sheet of white paper, and the metal plate is brought down upon the same with some pressure; all superfluous ink is at once pressed out, and after a pause of a few seconds to allow the warm ink to cool and to become set, the plate is again raised, and a beautifully shaded print is the result, in which the shadows and half-tones are formed by layers of ink of different thicknesses. For inasmuch as the ink is of a transparent character, and there is more or less of it deposited upon the paper according to the depths of the hollows in the engraved plate, so the half-tones are rendered with perfect gradation and fidelity, while in the high lights almost all the ink having been pressed away and removed, there remains nothing but the white paper which forms the basis of the print.

By printing at once from many plates (for a gelatine matrix will yield several dozen of them), photographs may be printed at the rate of some thousands daily, without of course the assistance of light in any way. Moreover, the productions are of so perfect and delicate a nature as to be confounded actually with silver prints, being at the same time absolutely permanent. We are glad to say that this method is also being worked practically and extensively in this country, as also in France and America, and will, without doubt, be the process of the future; for it is indeed the only mechanical process by means of which photographs may be rapidly produced, possessing the same degree of excellence as the beautiful, but alas! too fleeting, albumenised pictures.

H. B. P.

PHYSIOLOGICAL LABORATORIES IN GREAT BRITAIN

THE introductory paragraph with which you bring under the notice of your readers the very excellent description of the Physiological Laboratory at Leipsic by Dr. H. P. Bowditch, of Boston, begins with the phrase: "In England we have absolutely no Physiological Laboratory open for students." As this statement appears to me to admit of misconstruction, as leading to the inference that the present neglect of physiology in England is entirely due to the want of opportunities, it seems desirable to place before those of your readers who are interested in the subject, the actual position of this country as regards facilities for this kind of research.

There is, at all events, one institution in London, viz. University College, in which, for many years past, it has been possible for any man desirous of conducting experimental inquiries in Physiology or Pathology to do so; in proof of which I may refer to the experiments of the scientific committees of the Medical and Chirurgical Society on Apnœa and on subcutaneous injections; to my own experiments on the transmission of cholera to the lower animals, and on the influence of the respiratory movements on the action of the heart—all of which inquiries were made in the Physiological Laboratory of University College by persons unconnected with the Institution. In this enumeration I make no reference to the more abundant similar work which has been done by professors and students of the College, because my only object is to show that, as regards London at all events, it is many years since it could be said with truth that there was no Physiological Laboratory open to students.

At the present moment there are laboratories connected with one or two of the principal medical schools in this country to which students are admissible. In Edinburgh the Physiological Laboratory is fitted with all the instruments and appliances for research which are to be found in the laboratories of Germany; and for some time the students have been superintended in their studies by practical teachers, thoroughly versed in those methods of exact research which have been lately introduced into vital physics. In addition to the Physiological Laboratory, which is under the direction of Professor Bennett, the Professor of Medical Jurisprudence (Dr. Maclagan), and the Professor of Materia Medica (Dr. Christison) severally open their laboratories without charge, only requiring those who profit by them to meet the current expenses of research. Further, Dr. Arthur Gamgee, Lecturer on Physiology at the Royal College of Surgeons, has opened a new laboratory in which several separate inquiries are now being carried on. In Edinburgh, therefore, little can be said of want of opportunities; and here again the best proof of the existence of the means is to be found in the results attained, *i.e.* in the laboratory work actually performed by Edinburgh students during the last few years, as, for example, the researches of Dr. Fraser on Calabar Bean, of Dr. McDougall on the action of phosphorus, of Dr. Paton on the active principles of Broom, of Dr. Brunton on Digitalis, of Dr. Keith Anderson on the excretion of urea in typhus, of Dr. Young on the quantity of iron in bile, of Dr. Rutherford (now of King's College) on the vagus nerve, and others which might be mentioned, all of which possess the essential characteristics which constitute scientific value, though differing very considerably from each other in completeness. That so much has been already accomplished affords encouragement for the hope that as soon as the obstacles which still exist in the way of the student have been removed, Edinburgh will stand behind very few of the German schools of medicine in scientific productiveness. Of these obstacles, the most serious is that of expense. The large fees which are demanded, particularly for the physiological laboratory, have restricted the number of workers, the best of whom, as your correspondent, Prof. Stricker, so well pointed out in one of his recent communications, are not to be found either in England or Germany among the well-to-do.

It must be admitted that at the present moment our great London Schools are behind those of Edinburgh, as regards means of physiological and pathological research. There are, however, good reasons for anticipating that in a very few years the aspect of things will be entirely changed. In King's College a physiological laboratory already exists, to which I understand students are admitted. I am not aware to what extent it contains the necessary accommodation, but it is certain that those who work in it have at all events the supervision and aid of a teacher thoroughly conversant with the art of investigation, At Guy's, Bartholomew's, and St. Thomas's I hear that similar improvements are at all events in contemplation. At University College, which, as has already been said, has long afforded opportunities not to be had elsewhere, these have been much extended during the present year. The Physiological Laboratory now consists of three rooms, one of which, of large size, is devoted to students, one is employed as a place of research and for the preparation of materials for demonstration, while the third is used for such special purposes as require a separate apartment.

The movement towards a more practical method of teaching the theory of medicine, of which the facts I have referred to afford evidence, is a new one. In the course of very few years it may be confidently anticipated that great progress will be made, and that although we cannot in so short a time hope to compete with the splendid institutions which exist at Leipzig or at Breslau, where spacious buildings, costly instruments, and abundant material, are freely placed at the disposal of the student without charge and without respect to his nationality, or any other consideration except his competency, we may hope to produce results which may be of equal importance for the advancement of Science.

At the present moment, the want which perhaps presses even more than that of laboratories, is that of *workers* in physiology—that is, of men already drilled in chemistry and physics, and prepared to devote a few years of their lives to continuous physiological or pathological research. The reason why such men are wanting is no doubt in great measure that hitherto the opportunities for work have been denied them. Another, and perhaps more efficient reason, is that the statement which is so often repeated in lectures, that medicine is based on physiology, is not really believed or accepted. Consequently, young physicians, instead of devoting their time and energies to research—whether conducted in the hospital wards or in the laboratory—spend the best years of their lives in the collection and exhibition of curiosities from the dead-house (miscalled pathology), in the compiling of masses of useless statistics, or in the performance of other drudgeries, as little conducive to their own improvement as to the advancement of medicine.

If it were not for the want of this scientific conviction, or, if I may venture to use the expression, scientific *faith*, the study of vital physics would make rapid progress in England, notwithstanding all the material obstacles which stand in their way. A dozen years of good work would place us again side by side with Germany, instead of being, as now seems possible, in danger of being overtaken by America.

This country still maintains its superiority over all other European countries in respect of medical and surgical skill, and has reason to be proud of it. But it is to be borne in mind that the men who exercise that skill were for the most part educated at a time when we could also compete with Germany in Science. As Science advances, its influence on practice, now so difficult to trace, will increase. If we continue to undervalue it as we have done, shall we not also eventually lose our practical pre-eminence?

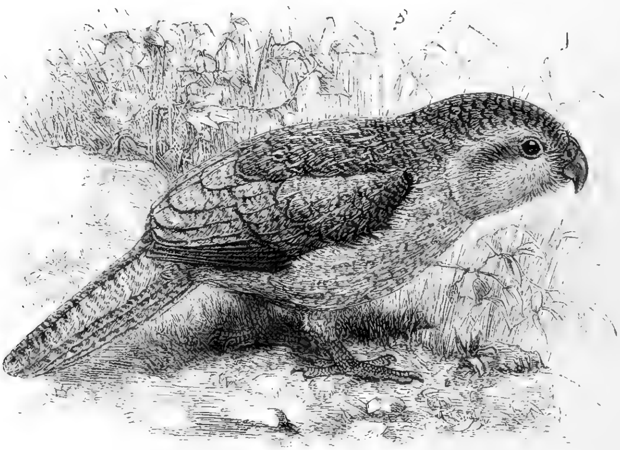
J. BURDON SANDERSON

NEW ZEALAND ANIMALS IN THE ZOOLOGICAL SOCIETY'S GARDENS

AT a recent examination for the Natural Science tripos at Cambridge, one of the pieces of information asked for in vain by the examiners was, I am told, "some account of the chief peculiarities of the Fauna of New Zealand." It so happens that the series of animals of our antipodean colony in the Zoological Society's Gardens is at the present moment unprecedentedly complete, and had the young gentlemen of Cambridge paid them an attentive visit, would have furnished ample materials for a proper answer to the examiners. I propose, therefore, to offer a few remarks upon them, and to make them the basis of some sort of answer to the question above mentioned.

Mammals in New Zealand there are none, except introduced species and bats, so it is not in this class of the animal kingdom that the visitor to the Society's gardens will find examples of New Zealand animals. There are, it is true, traditions and reports of some sort of "native rat"* having been occasionally met with, but no one has yet been able to produce a specimen of it, and after all, when captured, it may turn out to be only a stray individual of that cosmopolitan errant *Mus decumanus*. There are also marine mammals, both seals and whales, to be met with in the surrounding seas. But no terrestrial mammals, except bats, are indigenous to New Zealand, and for a country of such size, and situated in such latitudes, this is certainly a very remarkable and indeed unparalleled peculiarity.

With the next class of Vertebrates, however, the case is quite different. Bird-life, although according to the general evidence of the settlers not individually abundant, cannot be said to be badly represented in New Zealand. Dr. Otto Finsch, to whom we are indebted for the most recent summary of the birds of these islands,† gives 155 as the number of well-determined species hitherto met with, and there are, doubtless, a few more still to be made out, which will probably not long escape the grasp of



KAKAPO, OR GROUND PARROT

several excellent naturalists who are now at work on the fauna of their adopted country. Of these 150 species, one third, or perhaps rather more, are found only in New Zealand. But what makes its bird-life still more peculiar, is that the greater part of these 50 species belong to some 17 or 18 generic forms which are quite unknown elsewhere. And several of these forms (such as *Heteralocha*, *Strigops*, *Apteryx*, and *Anarhynchus*) are of the most bizarre and extraordinary character.

Of the Huia bird (*Heteralocha gouldi*) I have already given a notice and figure in the pages of NATURE.* I am not aware that there is any other instance in the class of birds in which the difference between the bill of the two sexes is so great, though something of the same sort is exhibited in the Humming-birds of the genera *Grypus* and *Androdon*. The Huia bird in the Zoological Society's Gardens has recently moulted off its worn and injured plumage, and is now in excellent health and condition.

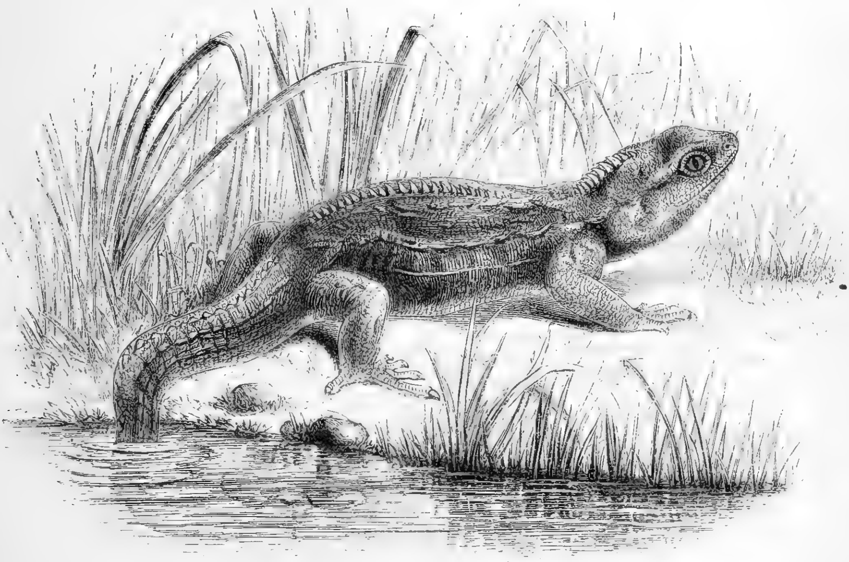
Of the very singular *Kakapo*, or Ground Parrot of New Zealand (*Strigops habroptilus*), I regret to say we have at present no example in the Society's Gardens. In the summer of last year one of these birds was successfully brought home from the Hokatika district, and was temporarily deposited by its owner in the Regent's Park Gardens, where it remained several months. But we were not able to come to terms as to its fair value, and the bird was consequently removed. The chief peculiarities of the *Kakapo* are its nocturnal habits, its abortive wings (which are nearly incapable of flight), the corresponding non-development of the crest of the sternum, and the possession of a facial disc, which gives it somewhat of an owl-like appearance. It is, however, a true parrot in the most essential part of its structure, and its food is strictly vegetable. During its sojourn in the Zoological Society's Gardens, it was fed principally upon corn and seeds of

* Vol ii. p. 146, June 23, 1870.

* See "Dieffenbach's New Zealand," vol. ii., App. p. 185.
† Ueber die Vogel Neu-Seelands. Von Dr. O. Finsch in Bremen. Journ. f. Ornith., 1870, p. 241.

various sorts. The colour of this bird is of a bright green, freckled with black, which is said to assimilate it exactly to the mosses of the New Zealand forests where it is found. Although disappointed in not retaining possession of the example of this parrot which has been already in the Gardens, we are in great hopes (from intelligence lately received from New Zealand) of the approaching arrival of other individuals of this rare bird.

The Kiwi or Apteryx, which I mentioned above as a third remarkable form of New Zealandian bird-life, has long been represented in the Zoological Society's living collection. In December 1857, Mr. Eyre, then Lieut.-Governor of the Colony, presented to us the first example of this remarkable form that had ever been brought alive to Europe. This bird is a female, as has been evidenced by her producing enormous eggs for several years in succession. The first of these eggs was deposited in June 1859, since which time she has usually laid two in the spring of every year, at intervals of about a month between them. The egg of the Apteryx when first deposited weighs about $14\frac{1}{2}$oz.; it is smooth and of a dirty white colour, and measures $4\frac{3}{4}$in. in length by $2\frac{9}{10}$in. in breadth. As the weight of the parent bird is only about 60 oz., it will be seen that the weight of the egg is nearly equal to one-fourth of the bird, a fact, I suppose, quite without parallel in the animal kingdom. Since the acquisition of the female, two additional specimens of the Apteryx, both of the opposite sex, have been received: one in 1864, presented by Major Keane, and a second in 1865, presented by Mr. Henry Slade. The female continuing to produce eggs after the males had been placed in her company, we were in hopes of rearing young Kiwis in the Gardens, especially as on more than one occasion the male, as is the custom among Struthious birds, commenced to incubate. This operation he performed by squatting closely on the egg placed between his feet, so that its long axis



TUATERA LIZARD

was parallel to that of his body. Unfortunately, however, in no case has there been any result, and the eggs when examined have shown no appearance of having been impregnated. And at length our sole surviving male fell a victim to the exemplary zeal with which he performed the duties of incubation. After sitting upon one of these huge eggs for upwards of six weeks, he died, probably from exhaustion, so that the original female, received in 1851, is at present the only representative of the species in the Society's Gardens.

Besides the above-mentioned specimens of Mantell's *Apteryx* (which is probably not really different from the original *Apteryx australis* of Shaw) the Zoological Society have recently received a single living example of the undoubtedly distinct Owen's Apteryx (*Apteryx owenni*). This bird arrived in July 1869, having been forwarded as a present from the Acclimatisation Society of Otago. It is readily distinguishable from the ordinary species by its smaller size, spotted feathers, and the softer and more fluffy plumage, but is closely allied to it in general structure and in all other peculiarities.

The fourth bird that I mentioned as one of the more remarkable bird-forms inhabiting New Zealand, has not yet been received in this country in a living state, indeed it is only quite recently that naturalists have become perfectly acquainted with the eccentricity of its structure. It is a small wading bird, allied to the Shore-plovers, but possessing the extraordinary feature of having the end of its bill curved towards the right. By the examination of the chick of the *Anarhynchus frontalis*, as this singular bird is called, Professor Newton has recently shown that this abnormality commences from the egg.* Such instances of asymmetrical structure are very rare amongst the more

* Proc. Zool. Soc. Nov. 15 1870, p. 674.

highly organised animals, indeed I am not aware of any similar instance among birds.

Besides the birds above-mentioned, the Gardens contain the only examples ever received in Europe of the *Kaka* Parrot (*Nestor hypopolius*), another form of bird-life restricted to the forests of New Zealand.

I must now say a few words about the Reptilian life of New Zealand. As regards this branch of the animal kingdom, the Zoological Society's Gardens cannot be said to be very well supplied; at the same time we have now in them a living example of what is certainly the rarest and most singular species of the reptilian class that inhabits these islands. This is the Tuatera Lizard (*Sphenodon punctatum*), of which I have already given a notice in a former article in this journal.* Dr. Günther will, I hope, forgive me for calling it a lizard, for in spite of his elaborate proof that it is utterly different from every other known form of the Lacertian order, I cannot quite agree with him that it is entitled to form an order of itself.

As regards the general character of the reptilian fauna of New Zealand, after mentioning the Tuatera, there is not much to be said. There are, I believe, no representatives of the orders of Tortoises, Crocodilians, or Ophidians to be met with in these islands. Besides the *Sphenodon*, the only other reptiles indigenous to New Zealand are about half-a-dozen small lizards belonging to the families *Scincidæ* and *Geccotidæ*. Some of these are of Australian character, the remainder are peculiar to New Zealand.

Of the class of Batrachians, only one member is known to exist in New Zealand—a frog (*Leiopelma hochstetteri*), not found elsewhere.

Fresh-water Fishes, which must also be taken into account when estimating the peculiarities of a land-fauna, are likewise not very abundant in New Zealand. Two forms, however, deserve special notice, as indicating a former land connection at however remote an epoch, between Australia and South America passing through these islands. These are *Protrotoctes*,† belonging to a group representative of the Salmonoids of the northern hemisphere, and *Galaxias*, belonging to a family allied to the Pikes (Esocidæ) which is likewise found in the rivers of Australia and Antarctic America. Nearly allied to *Galaxias* is a very curious form, recently described by Dr. Günther under the name *Neochanna apoda*,‡ but remarkable for the absence of ventral fins, and its mud-loving habits. This fish is restricted to New Zealand.

The peculiarities of the fauna of New Zealand, so far as is shown by its terrestrial vertebrated animals, may therefore be summed up somewhat as follows:—

1. The absence of all Mammals, except two species of Bats.

2. The presence of numerous forms of Bird-life not known elsewhere, such as *Heteralocha*, *Nestor*, *Strigops*, *Apteryx*, and *Anarhynchus*.

3. The absence of Reptiles, except two genera of lizards and the *Sphenodon punctatum*, which, according to some of the best authorities, has claims to constitute an order of reptiles *per se*.

4. The absence of Batrachians, except one species of frog not known elsewhere.

5. The paucity of fresh-water Fishes—few genera only being known—which are allied partly to Australian and partly to Antarctic American forms.

But before closing our summary, it must not be forgotten to be mentioned that almost within the historical period New Zealand was tenanted by upwards of a dozen species of Struthious birds, constituting a family *per se*, but allied to the Cassowaries and Emus of Australia and the Papuan Islands. We must therefore add as a sixth item:

6. The recent presence of a peculiar family of gigantic Struthious Birds, now extinct—the Dinornithidæ—restricted to New Zealand.

P. L. SCLATER

NOTES

In other columns will be found the reports which have reached us up to the present time from the different sections of the Eclipse Expedition. Notwithstanding the unpropitious weather at nearly all the stations, we trust that some observations have been made which will throw light on still unsolved problems of Solar Physics. It is with great satisfaction that all English astronomers will hear that M. Janssen performed his perilous balloon voyage in safety, and reached his destination in Algeria; although he does not appear to have been rewarded with the opportunity of taking any satisfactory observations.

The *Journal of Botany* states that the post of Curator of the Botanic Gardens, Calcutta, vacated by the death of Dr. Anderson, has been given to Dr. King, who has done some work in Indian botany, but is comparatively unknown in English botanical circles. This is the best-paid botanical appointment in England or any of its dependencies.

The following are announced as the probable arrangements for the Friday evening meetings at the Royal Institution before Easter, 1871, to which members and their friends only are admitted:—Friday, January 20th, Professor Tyndall, LL.D. F.R.S.; Friday, January 27th, Professor Odling, F.R.S.; Friday, February 3rd, W. Spottiswoode, Treasurer R. S.—Some experiments on Successive Polarization of Light made by Sir C. Wheatstone; Friday, February 10th, E. J. Reed, C.B.—On Some Fallacies connected with Ships and Guns; Friday, February 17th, James N. Douglas, Engineer to the Trinity House—On the Wolf-Rock Lighthouse; Friday, February 24th, Dr. W. B. Carpenter, F.R.S. &c.—The latest Scientific Researches in the Mediterranean and Straits of Gibraltar; Friday, March 3rd, Capt. Noble, F.R.S.—On the Pressure of Fired Gunpowder; Friday, March 10th, W. Mattieu Williams—On Rumford's Scientific Discoveries; Friday, March 17th, J. Norman Lockyer, Esq., F.R.S.—On the Eclipse; Friday, March 24th, Professor J. Clerk Maxwell, M.A., F.R.S.—On Colour; Friday, March 31st, Professor Max Müller, LL.D.—On Solar Myths.

The following gentlemen have obtained a first class in Natural Science at Oxford at the last examination:—C. Childs, Scholar of Merton, F. H. Champneys, Brazenose, F. W. Fison, Scholar of Christ Church, S. J. Sharkey, Scholar of Jesus.

The Natural Science Scholarship at Merton College, Oxford, has been awarded to Mr. Richmond of the Manchester Grammar School, and an Exhibition to Mr. Ferguson of the same school.

Prof. Agassiz announces that the Museum of Comparative Zoology at Harvard College, Cambridge, U.S., is prepared to furnish extensive collections of all the rocks and loose deposits found upon and about the Key and reefs of Florida; also complete collections of the Corals in fresh and well-preserved specimens, in exchange for recent and fossil corals from other parts of the world.

The *Pall Mall Gazette* states that a committee has been appointed, with Captain Beaumont, R.E., M.P., as president, and Lieutenant Grove, R.E., and Mr. Abel, F.R.S., as members, to carry out experiments on the utilisation of balloons for reconnoitring purposes. The former experiments on this subject, which were carried out at Woolwich and elsewhere a few years ago, were not attended with any useful results, and we believe the attempts which have been made during the present war to reconnoitre with balloons—an application not to be confused with the use of balloons for postal purposes—have not been more satisfactory. But the Americans on several occasions employed balloons to reconnoitre with fair success, and Captain Beaumont's committee may be able to throw some new light upon a subject which it certainly seems worth while to work out.

THE frost which has now lasted for a fortnight is the most severe that has been known in England since the memorable one of Christmas, 1860, that is, for exactly ten years. The lowest temperature at Blackheath was 15·3° F. on the night of the 24th December; but in the eastern counties the cold was more intense, being 8° at Hull, and nearly as low at Norwich, Nottingham, and Leicester. The highest minimum recorded by Mr. Glaisher in the *Gardener's Chronicle*, at any English station is 19·0°, at Leeds. In Scotland the minimum varied between 5·0° at Perth, and 19·2° at Aberdeen. The average was slightly higher in Scotland than in England. For the first fourteen days of the frost, the temperature scarcely rose above the freezing-point night or day, a very unusual circumstance in this country.

A SOCIETY has just been instituted under the designation of *The Society of British Archæology*. It originated in a meeting held on Dec. 9th in the rooms of the Royal Society of Literature, the proposed objects being "the investigation of the Arts, Archæology, History, and Chronology of Ancient and Modern Assyria, Palestine, Egypt, Arabia, and other Biblical Lands, the promotion of the study of the antiquities of those countries, and the preservation of a continuous record of discoveries now or hereafter to be in progress." Dr. Birch, of the British Museum, who occupied the chair on that occasion, explained that the proposed society would clash with none of the philological or exploration associations now in existence, but would have a distinct purpose—to concentrate and utilise the scattered materials connected with the geography, arts, and antiquities of the lands of the Bible, and to systematise the progress of Archæological research in England, America, and the Continent. The Society has already received the promise of the support of the most eminent living Biblical investigators, and another meeting will shortly be summoned for its complete establishment.

UNDER the title of "Science Education Abroad," Principal Dawson of M'Gill University, Montreal, republishes his Annual University Lecture, of the session 1870-71. After reviewing the state of scientific education in foreign countries from a Canadian point of view, as exhibited by the present condition of the various institutions for the spread of Science in Great Britain, the United States, Germany, and Switzerland, he contrasts with this the want of Science teaching in Canada. With the exception of two or three small and poorly supported agricultural schools, he states that the Dominion does not possess a school of practical Science, notwithstanding its mining resources, second to those of no country in the world. In the M'Gill University itself some part of Natural or Physical Science is studied in each year of the College course; but this falls far short of providing the full measure of the higher Science education required for the development of the resources of the country.

PROFESSOR M'NAB has been pursuing his investigations on the Transpiration of Watery Fluid by Leaves, to which reference was made a short time since in our columns.* The plant used in all the experiments was the common laurel (*Prunus laurocerasus*), and the fluid to test the rapidity of the ascent lithium citrate. The following are some of the more important results arrived at:—The total quantity of water in the leaves was found to be 63·4 per cent.; but of this, the proportion which could be received by calcium chloride, sulphuric acid, or by the action of the sun, was only from 5 to 6 per cent.; hence Dr. M'Nab calculates the amount of transpirable fluid in the stem and leaves to be between 6 and 7, the amount of fluid in relation to cell-sap to be between 56 and 57 per cent. The rapidity of transpiration he found to be in sunlight 3·03 per cent. in an hour; while in diffused daylight it was only ·59, and in darkness ·45 per cent. in the same time. These experiments were made when the plant had access to water by means of its stem. When the leaves were exposed without any means of supplying themselves again, the following results were obtained:—In a saturated atmosphere in the sun, 25·96 per cent. was transpired in an hour, in a dry atmosphere in the sun 20·52 per cent. In the shade, the numbers were reversed—viz., in a saturated atmosphere nothing, in a dry atmosphere 1·69 per cent. When immersed in water, the leaves absorbed 4·57 per cent. of their weight in seventeen hours, in a saturated atmosphere nothing whatever in eighteen hours. The under surface of the leaf transpired nearly ten times as much as the upper surface.

* See NATURE, vol. ii. p. 515.

WE are very glad to see that the second series of penny science-lectures delivered in November in the Hulme Town Hall have been reprinted. They embrace:—Coral and Coral-reefs, by Prof. Huxley; Spectrum Analysis, by Prof. Roscoe; Spectrum Analysis in its relation to the Heavenly Bodies, by Dr. Huggins; and On Coal, by Mr. Boyd Dawkins. The reports have all been revised by the respective lecturers; and being published at one penny each, ought to have a very large sale. We cannot conceive a greater aid to scientific teaching than the circulation of these lectures; both for the information they contain, and as models to lecturers of what scientific lectures to working men should be.

THE last number of the *Bulletin de la Société Royale de Botanique Belgique* contains an interesting paper by M. Devos on the plants naturalised in, or introduced to, Belgium. Of the 1,566 phanerogams recorded for that country, no less than 512 are supposed to have been introduced. Of these 91 are from southern Europe, 137 from the east, 14 from central, and 5 from north Europe; "alpine regions" have furnished 16, 34 are from America, and 5 from Africa; while the native countries of the remaining 210 are unknown. The distribution of each species is traced out with reference to its occurrence in other countries under similar circumstances; and the paper is a valuable contribution to phytogeographical science.

AMONG the curiosities of scientific literature a little work, published a few years since, must find a place. It is entitled "Principles and Rudiments of Botany, delivered according to an Iulian system of arrangement and Iulian method of classification; by C. R. W. Watkins, Gent., late Captain in the Bombay Army." These "principles and rudiments" are here, according to the preface, delivered in language "better adapted for the intellectual amusement and instruction of young persons of both sexes" than that employed in previous works; and "Botanical science" is "rendered more agreeable to students in modern times." The following extract will give a faint idea of the mode in which these promises are fulfilled, and also of the contents of the volume:—"The pink (*Dianthus*) has four or five idola; ten to twenty ikona, and twenty to forty petala. The flowers are few, and di, tri, quinque ligate, and they terminate separately and irregularly. The Sweet William (*Dirythme*) has two idola, ten ikona, and five petala. The flowers are numerous and chorovinkulate, and the mode of gemmation comprises several synterminal and equimarginal chorrythma, or conturrythma. They cannot, therefore, be of the same genus; because the numerical indices, and typical characters of each gemmos, or hermaphral gemm bud of the two kinds of plants, are not symbolical; but differ, as well as the mode of gemmation, more widely than the specific, and physical circumstances of their constitutional, or peculiar veget-organical structure."

THE laws which formerly existed in Scotland, and are still enforced in Denmark, to compel the extirpation of the Corn Marigold (*Chrysanthemum segetum*), have their parallel in New Zealand, in some parts of which it is a punishable offence to allow the growth of thistles. In the colony of Lyttelton proceedings were taken, during the present year, against a gentleman for having neglected to eradicate certain thistles, after having been requested to do so. The defendant alleged that men had been employed for ten days in striving to exterminate them, and that ten donkeys were kept for the sole purpose of eating off the tops of the thistles. The Bench, however, were of opinion that no adequate steps had been taken since a previous conviction, and imposed a fine of 5*s*. per day from that date.

WE learn from Dr. Müller's last report of the Melbourne Botanic Gardens that the noxious "Cape Weed" (*Cryptostemma calendulaceum*), is becoming suppressed in his vicinity by the gradually denser growth of lucerne, clover, and grass. The plant was noticed as an inexterminable weed of Australia, by Baron von Huegel, in 1833. It would appear that more than one plant is known as "Cape Weed," as another Composite (*Hypochœris radicata*), is so called in New Zealand, where, in the neighbourhood of Dunedin, it is spreading to a serious extent.

A WRITER in the *Field* for Dec. 17, advocates the cultivation of *Symphytum asperrimum* as food for cattle. He recommends that the plants should be set about two feet six inches from each other; and that the most forward of the leaves should be plucked as they develop. Horses are very fond of it, and it is beneficial in its effects upon them. It is not recommended that it should be made store of, but the leaves should be gathered and eaten fresh. It will be remembered that Prof. Buckman, when at Cirencester, instituted some experiments upon this plant, which led him to the conclusion that it was not specifically distinct from the common Comfrey (*S. officinale*); and it is therefore probable that the latter would be equally suitable for cattle. *S. asperrimum* is a plant of very rapid growth; boiled as a vegetable it is palatable, and in Germany it is a favourite ingredient in salad.

AMONG the various notes upon tree-worship which have lately appeared, no mention has been made of the Cotton-tree (*Eriodendron anfractuosum*). Of this Dr. Macfadyen, in his "Flora of Jamaica," writes as follows: "Perhaps no tree in the world has a more lofty and imposing appearance, whether overtopping its humbler companions in some woody district, or rising in solitary grandeur in some open plain. Even the untutored children of Africa are so struck with the majesty of its appearance, that they designate it the God-tree, and account it sacrilege to injure it with the axe; so that, not unfrequently, not even the fear of punishment will induce them to cut it down. Even in a state of decay it is an object of their superstitious fears; they regard it as consecrated to evil spirits, whose favour they seek to conciliate by offerings placed at its base."

AN early mention of tobacco is that in Hakluyt's "Voyages," by M. Jaques Carthier, in 1534. Speaking of the people of "Hochelaga, up the river of Canada," he says, "There groweth also a certain kind of herbe, whereof in Sommer they make great prouision for all the yeere, making great account of it, and onely men vse of it, and first they cause it to be dried in the Sunne, then weare it about their neckes wrapped in a little beasts skinne made like a little bagge, with a hollow peece of stone or wood like a pipe, then when they please they make pouder of it, and then put it in one of the ends of the said Cornet or pipe, and laying a cole of fire upon it, at the other ende sucke so long, that they fill their bodies full of smoke, till that it commeth out of their mouth and nostrils, even as out of the Tonnell of a chimney. They say that this doth keepe them warme and in health, they neuer goe without some of it about them. We ourselves haue tryed the same smoke, and hauing put it in our mouthes, it seemed almost as hot as Pepper."

As a general rule, plants which are casually introduced to, and become firmly established in, any country, are by no means to be regarded as useful acquisitions; some of the worst weeds of cultivation may be found among them. An exception to this, however, may be noticed in *Lespedeza striata*, "Japan clover," or "wild clover," as it is called in the localities to which it has introduced itself. It has recently sprung up in great abundance in all parts of the Southern States, and has proved a great acquisition to the farmers. The roots, which are long and fibrous, penetrate and flourish even in sandy roads and in yards; and a single root will send out as many as six hundred branches. The *Lespedeza* is a close-growing plant, covering the ground as with a carpet of green, and is taking the place of the sedges and other weeds upon the waste lands and clearings. Cattle, horses, and sheep eat it greedily; and it is in every way an important addition to the fodder-plants of the country.

A CONTRADICTION is given to the reported discovery of coal in the Bellary district in Madras.

ON the 3rd of October the Faculty of Science and Polytechnic School were opened at Quito in Ecuador. There is reason to believe that these establishments of the repudiatory republic are more pretentious than real.

CINCHONA has so fully succeeded in the Neilgherry Hills in India that the first shipment of bark from a private plantation to the extent of 4,000 lbs. is taking place. The Government promoted Cinchona plantations chiefly for the supply of India, but they are already engaging in the home trade.

A RARE discovery has been made near the port of Mejillones in that district of the rainless desert of Atacama belonging to Bolivia, of a spring of fresh water. This has been granted to the discoverer for ten years, and then to become the property of the State.

ON the 18th of October, at 5 P.M., a slight earthquake was felt at Salvador in Central America. There had been heavy rains for some days.

THE Queensland Acclimatisation Society, under the patronage and with the assistance of his Excellency the Governor and other influential persons in the colony, appears to be in a satisfactory condition, both financially and with regard to the work done, as well as the earnestness and ability of its workers. In the park belonging to the society a considerable number of foreign trees have been introduced, and amongst them the splendid tree of Madagascar (*Poinciani regia*), which, we are told, is being raised by hundreds. This success of foreign trees is very gratifying at a time when the question of want of shade trees is a matter of much interest, not only in Queensland, but also in other colonies. The Shola (*Æschynomene aspera*) is likewise amongst the recently-introduced plants which promise success. It is a native of India, and is well known on account of its light wood being used for making the "pitte" hats, so much used in tropical countries. Among British birds introduced by the Society, and which survived the voyage from London, the blackbird, thrush, starling, rook, sparrow, and lark, have been liberated in the Botanic Garden; but at the time the report was drawn up little could be said as to their condition or whereabouts, except that one pair of sparrows were then rearing their second brood in the heart of the city. Large numbers, also, of Chinchilla rabbits, and of the wild English breed, have been turned loose on the islands of Moreton Bay, but care has been taken to keep the different kinds separate.

IT is not a little remarkable that *Corchorus capsularis*, one of the plants yielding the jute of commerce now so largely imported and used in the manufacture of carpets, and also largely used in India for gunny bags, should, though growing wild in Sumatra, not be cultivated in that island. The bags in which Java coffee is exported are made of this fibre. Large quantities of these ready-made bags are annually sent from Bengal, even to Java.

THE ECLIPSE EXPEDITION

As we intimated last week, the weather was more or less unfavourable at nearly all the stations for the observation of the Total Eclipse of Dec. 22nd. We give, in another column, an account of the preparations made by the Sicilian department of the Expedition, received by us. The following account of the results obtained at some of the other stations is compiled chiefly from reports furnished to the *Times* and *Daily News*.

From Cadiz we have an interesting account by the Rev. S. J. Perry, as follows:—

"The situation of San Antonio is found to be lat. 36° 37′ 13″ N., long. 24′ 15″ W. of Greenwich. Time signals were daily received from the San Fernando Observatory, and all our chronometers carefully rated by Capt. Toynbee. Our thirteen observers were distributed as follows: Mr. Moulton, of Christ's College, Cambridge, with Mr. Baines, of Oxford, were to observe with the polariscope at Sanlucar, the extreme W. point on the Spanish central line of totality, and 12 miles N.W. of San Antonio. Near Xeres, 5 miles N.E. of San Antonio, were stationed Mr. P. Naftel, for an eye sketch of the corona, Mr. F. C. Penrose to sketch the same as seen through a telescope, and Mr. Abbay, of Wadham College, Oxford, to observe with the spectroscope. Mr. W. Smyth sketched near Arcos, 17 miles E.N.E. of San Antonio, using a telescope of the same aperture as that of Mr. Penrose. The rest of the observers remained at San Antonio. At this station the spectroscopic observers were Capt. Maclear, R.N., and myself, assisted by Mr. Hostage. Polarisation was to be observed by Mr. Hudson, of St. John's, Cambridge, and Mr. Ladd, optician; and an eye sketch of the corona to be made by Mr. Browne, of Oxford. The weather has been unexceptionally bad ever since our arrival, the only fine day being the 21st. Our observers were therefore spread out as much as possible, in hopes of not failing altogether on account of bad weather. The results justified our anticipations. The fine weather of the 21st lasted but a day, and at two A.M. of the 22nd the clouds and rain returned. At San Antonio a break only came some 48^s after first contact, when a distinct notch was observed on the solar disc. This break was only a change from thick cloud to thin cirrhus, but we were enabled to observe the time of contact of the limb of the moon with several of the more remarkable solar spots. In the north the sky was partially clear, but in the south no part of the heavens was free from cloud. A very striking change of light on the landscape was noticed when little more than three-fourths of the solar disc was covered, and a chill was felt by all. The thermometer observed by Capt. Toynbee fell 3°F. from the commencement to totality, and rose again 1·7° before the end of the Eclipse. The barometer was falling rapidly all the time of the Eclipse, and also afterwards, at the rate of 0·04 in. an hour. The wind was W. by N. true. During totality it lulled, but freshened afterwards with very heavy rain. The moment of totality approached, and no chance remained of even a momentary break in the thin cirrhus that enveloped the sun, and obscured most of the southern heavens. As the crescent became thinner, the cusps were observed first to be drawn out a length of several minutes, and then blunted; the well-known Baily beads were formed, and the corona burst forth more than 20^s before totality. Viewed through a telescope of very moderate dimensions the spectacle was grand, but the cirrhus clouds destroyed almost all the grandeur of the effect for the naked eye. The red prominences were numerous, but none apparently very remarkable; Mr. W. H. Browne, of Wadham College Oxford, considers their colour to have been of a bright yellowish red tint. The same observer notices that the corona was perfectly free from striation, outline distinct, and approximately quadrilateral, but extending farthest in the direction of first contact. The brightest part of the corona appeared to the unassisted eye to be scarcely more than one-tenth of the sun's diameter, fading rapidly when one-fifth, but being still clearly visible at seven-eighths. Some observed two curved rays, but the general appearance was that of a diffuse light interrupted in four places distinctly, and in a fifth faintly, by dark intervals. The corona was white, and rendered faint by the clouds. The darkness was never sufficient to prevent sketching with comfort without the aid of a lamp. Venus alone was visible. Totality ended by the formation of Baily's beads, and the corona was visible to the naked eye 15^s or 16^s after totality. The corona was seen for $2^m\ 50^s$, totality lasting less than $2^m\ 10^s$. The clouds obscuring the sun appear to have destroyed almost all chance of detecting any except atmospheric polarisation. Mr. Ladd remarked that the polarisation was stronger on the corona than on either the moon's surface or the cloudy sky.

"No report has as yet been received of the polarisation observations at Sanlucar. The observations with the spectroscope were also greatly interfered with by the cirrhus, and the best instrument was rendered entirely useless. The intensity of the light from the corona, as seen through the clouds, could not, I think, have been more than one-eighth of that of the bright moon, if so much, and, consequently, I was unable to detect the faintest trace of light through the three compound prisms I was using. The chances of observing satisfactorily, considering the state of the sky, were greatly diminished by the largeness of the direct image given by the Cassegrain I was compelled to use. Knowing that an unfavourable sky would render observations with a powerful spectroscope quite impracticable, I desired Captain Maclear to observe with a small direct vision Browning spectroscope, attached to a four-inch achromatic by Jones, mounted equatorially. The slit was placed radial at the centre of the east limb, and close to it, and immediately totality commenced the ordinary solar spectrum was replaced by a faint diffused light, and bright lines near C, D, b (or E), and F. No absorption bands. The slit was then removed to a distance about 8′ from the limb, and the same lines remained visible. The centre of the moon was next tried, and the bright lines were still seen, but only half as strong as before. The slit was then placed 8′ outside the W. limb, and the lines became as strong as before, and were C, D, one three-quarters of the distance from D to E, and another half way between E and F. Lastly, placing the slit near the sun (on a prominence) two new green lines, and a very brilliant line beyond F, were added to those already visible, but the line near E may have disappeared. The lines seen on the moon were, I suppose, due to the diffusive power of the cirrhus clouds; and the same may perhaps be true of the apparent coronal lines.

"Mr. Abbay, observing at Xeres with a spectroscope of two prisms of 45°, belonging to Professor Young, saw the bright lines C, D, F; and afterward F, and a line rather more bright than F, at some distance on the less refrangible side of B, C not noticed then. These two observations were, I think, taken at points external to the prominences, but I cannot at present speak with certainty, as no note to that effect is entered in the memorandum I received. A comparison of these observations with those of other observers more favoured than ourselves will doubtless lead to valuable results. Shortly after totality the clouds thickened still more, and nothing further could be observed."

The view of the Eclipse obtained near Arcos is described as very magnificent; a sketch was made there by Mr. Warrington Smyth. At the American station near Xeres there was a break in the clouds, which lasted somewhat more than half the totality. But Lord Lindsay's party was the most favoured in this country, having seen the sun through a rent in the clouds for five minutes, and this time embracing the whole of totality. Mr. O. Airy and

Mr. Hammond, of Trinity College, Dublin, observed at San Antonio, and were kindly assisted by Lieutenant P. H. Worgan and Mr. T. H. Atkinson, of H.M.S. *Lee*.

Another correspondent, from Cadiz, writes to say that Lord Lindsay succeeded in taking several excellent photographs from a vineyard belonging to Mr. Campbell, half way between Port St. Mary's and San Lucar.

The American party at Xeres saw the totality for about a minute.

From Gibraltar, Mr. R. M. Parsons sends the following report :—

"The party that left England for the purpose of observing the Total Eclipse of the sun at Gibraltar—namely, Messrs. Carpmael, Gordon, Lewis, Buckingham, Beasley, Harrison, Anson, Abbatt, Talmage, and myself—disembarked from Her Majesty's ship *Urgent* on the 14th Dec., and all but the three last-mentioned proceeded to Estepona, a village in Spain, about thirty miles north-east from Gibraltar, and situated in the central line of totality. By this division of the party an additional chance was afforded of observing the phenomenon in case of bad weather, and Estepona offered the advantage of some 13^s longer time of total obscuration than Gibraltar, a condition very desirable for the particular class of observations required by some of the party. The weather at Gibraltar was wet and cloudy almost from the time we landed until the day before the Eclipse, when a strong breeze W. by N. gave a beautifully clear sky, which lasted till about midnight. Mr. Talmage, the director of the Leyton Observatory, and I, determined to observe from the Moorish Castle if the atmospheric conditions of the 21st should hold good on the 22nd ; but I arranged to receive constant telegrams of the weather from Europa Point on the morning of the 22nd, and conveyance was provided to move the instruments at the latest practicable period, in case any other position afforded better chances of success. Mr. Talmage was to take angular measurements of Saturn, if seen through the corona, Mr. Abbatt to sketch the corona, and I was to examine it with a polariscope. The westerly wind increased in force on the 22nd, but brought with it scud and dense clouds across the Bay from the Spanish mountains; everywhere these clouds were massed in the sky, separated by small intervals of hazy blue. The last telegram was received from Europa at a quarter-past eleven, forty minutes before commencement of totality, stating 'sky quite overcast, heavy clouds moving south-east, sun hardly visible.' This, together with the circumstance that the Rock did not appear to affect the clouds which were moving under the influence of a westerly wind, led me to conclude that the chances of good vision were equal at any position on the Rock. After waiting on the Line Wall for these telegrams, at which place I failed to observe the first contact, while Mr. Talmage failed in the same endeavour at the Moorish castle, I joined him there, leaving Mr. Abbatt with his telescope erected on the flat roof of a house about a quarter of a mile west of the castle. The cloud which caps the Rock of Gibraltar, the summit of which is 1,396ft. above the sea, during east winds, or Levanters, leaves this comparatively low level clear. About 30^s before the commencement of totality, a hazy blue break in the clouds enabled us to see the thin bright crescent of the sun, but unfortunately this patch of hazy blue sky, which favoured others for a few seconds, came a little too early in front of our position, and it was followed by a dense cloud, behind which the entire phenomenon of totality was hidden from us. The darkness was considerable, but not so great as when I observed the Total Eclipse of 1860, at Nisqually, in an unclouded sky. Then a lamp was necessary to enable a white-faced pocket chronometer to be read ; yesterday I could see the divisions distinctly at the distance of eight inches without such aid. Mr. Abbatt had the good fortune to see the corona and some red prominences, but only for about two seconds before they were lost in the same dense cloud ; he estimated the breadth of the corona at about a sixth part of the moon's radius. Professor Newcomb, of the United States' Expedition, was able to see all four contacts, and to take several measurements that were necessary for the work he has in hand ; he also caught a glimpse of the corona, but says he could make no use of it.

"Mr. Lewis states that the party at Estepona only saw the total phase through a break in the clouds for about 10^s or 15^s, when it was covered by light cloud. Mr. Buckingham, at Estepona, states that they had there heavy rain ; he could take no photographic pictures, but Mr. Carpmael had observed three bright lines in doubtful positions, and Mr. Lewis found the corona polarised ; the rest of the party had negative results. Mr. Harrison, who was distant a mile from the others, did not see the total phase. Mr. Anson had not time at the moment to sketch what he saw, but probably may be able to do so from memory, and Mr. Fison, who had then joined the party, had no opportunity of obtaining satisfactory observations."

Mr. Abbatt reports :—"In no part did the corona or the prominence extend beyond 1-8th or at most 1-6th of the moon's radius beyond the limb. I thought the moon darker than the sky. I noticed four high red prominences—there were more, but when, for an instant, I took my eye off the telescope a dense black cloud had obscured everything till the narrowest streak of the sun appeared on the western side, and nothing but the ordinary phenomenon of a partial eclipse was to be seen. The darkness during totality was not so great as I expected it would be. Two stars were seen, one near the sun and the other overhead, but I can get no further information as to their exact position."

Another observer writes as follows :—"The eclipsed orb presented itself through a rent in the clouds not greater in area than ten times that of the disc of the moon's shadow. That part of the opening which was above the eclipsed orb was clear like the sun at twilight, and in it were visible to the naked eye the planets Venus, Mercury, and half a dozen stars. The remaining part was covered with a thin haze. The moon's shadow appeared to the eye, assisted by a somewhat weak binocular glass, to be a dark circular disc with an even boundary and of uniform shade. Within the corona, and touching the circumference of this shadow, appeared five or six spots of brilliant carmine, varying in form and size and at irregular distances apart. Two of these spots, or 'red flames,' as they are called, on the eastern side of the disc, and at about 55° and 80° respectively from the vertex, seemed decidedly the largest and most prominent ; they were tongue-shaped, and protruded about 1-6th the width of the corona. In their neighbourhood the corona was brightest and widest. There, too, the rays of the corona appeared to be gathered more distinctly into groups than elsewhere, faint shadows being visible between the groups. The corona consisted of brilliant rays of extremely faint prismatic hues ; these rays at first sight appeared pretty evenly distributed all round, but closer examination seemed to detect the fact of there being bundles of rays in nearly regular groups. The width of the corona was about 1-8th the apparent diameter of the moon's shadow. It was very nearly concentric with the disc of the shadow ; its boundary was well defined, but 'jagged ;' the perimeter, except opposite the two most prominent red flames above-mentioned, where the boundary slightly protruded, was circular."

From Seville, we have a report from M. E. A. De Cosson :—

"The Eclipse began at 10.30 A.M. (Seville time). At 10.45 one-sixth of the sun's diameter was obscured ; at 11.15 one-half ; and at 12 the Eclipse was total. At 12.10 it began to rain, and the sun was lost to sight until the conclusion of the eclipse, which occurred at 1.30 P.M. The eclipse was total for 70^s and the effect was very striking, the whole sky becoming of a lurid purple and very dark. The birds were hushed and frightened, and the charcoal burners' fires in the mountains, some five miles distant were plainly visible."

At Oran the weather appears to have been still more unpropitious than at the European stations. For the observations with the spectroscope, this section of the Expedition was provided with a 6-inch equatorial, of eight feet focal length, by Cooke, of York, lent by the Royal Observatory at Greenwich, to which was adapted an extremely ingenious recording spectroscope, the invention of Dr. Huggins, who himself observed with it; the management of the telescope devolving upon Captain Noble. A second smaller instrument, of 4 inches aperture, with a somewhat similar recording apparatus, was entrusted to Mr. W. Crookes, F.R.S., the Rev. F. Howlett attending to the telescope itself. The polariscopic observations were undertaken by Captain Salmond, R.E., and Lieutenant Collins, R.E.; the instrument of the former being attached to a telescope of about thirty inches focal length and $2\frac{1}{2}$ inches aperture; that of the latter to another of 6 inches aperture. General observations, sketching of the corona, &c., were to have been made by Mr. Carpenter, of Greenwich Observatory, with an exquisite 3-in. Dolland equatorial; by Mr. Hunter, with a 4-in. of rougher construction; by Lieut. Wharton, R.N., of the *Urgent*, with a $2\frac{3}{4}$ achromatic, mounted temporarily equatorially; by Admiral Ommaney, with a small table telescope; by Lieut. Ommaney, R.E., with a binocular field-glass, on cards arranged for the purpose; and by the ship's officers generally, with such telescopes as they could command. The 6-in. and 4-in. equatorials were erected under a tent; the rest were employed more or less in the open air. Prof. Tyndall had established himself on a neighbouring fort, some 500 or 600 yards from the rest of the party, with a 5-in. telescope by Dallmeyer, which had been used by Mr. Dela Rue at the Total Eclipse in Spain. His observations were to be of a general character.

The atmospheric conditions in Oran in December are exceedingly like those of a very wet and windy English autumn, the day of entering into port having been the only moderately fine one experienced at all. The wind particularly was tremendous. On the 21st the observatory tent was blown down, and it was only by great exertions that the instruments themselves were saved from destruction.

The morning of the 22nd broke very doubtfully, heavy driving clouds obscuring the sun. The party were, however, all at their posts betimes, and arranged their various instruments long before the predicted instant of first contact. The clouds obscured the sun at this particular time; but soon, through a rift in them, the dark limb of the moon was seen encroaching on the sun's disc. Observation after this became very trying, as it was only possible at distant intervals to glimpse the progress of the moon, as she gradually advanced in her path. Spectroscopic observation, or even polariscopic observation, was practically impossible. Finally a glimpse was caught of the sun some eight or nine minutes before totality as a very thin crescent, and then every chink and cranny in the clouds closed up, and one dense and impenetrable pall covered the earth. Nothing remained now but to go out of the tent and observe the effect in the open air. It was certainly very striking. As the moment of totality approached, the western sky turned of an awful livid purple, the clouds over head assuming a black tint. As the shadow swept over the earth, the eastern sky became obscured, while the western horizon lighted up like the grey dawn of a dull autumn morning. At no time, however, during the totality, was it difficult to see the seconds on the face of a watch. The light was that of a cloudy evening, about an hour after sunset. One curious effect was observed, the apparent contraction or closing in of the celestial vault. Speedily, however, the dawn in the western horizon spread over the heavens; but the sun did not reappear again for at least half an hour after totality. M. Janssen, the French astronomer, who escaped, at the risk of his life, with his instruments in a balloon from Paris, was stationed on a mountain some seven miles from Oran. He can have seen nothing whatever of the phenomenon which he had braved so much to observe.

Another account from the same station states that the earlier stages of the Eclipse were seen and a photograph taken, but ten minutes before totality a dense bank of clouds came over the sun, which extinguished all hope, and rendered useless the laborious preparations of many weeks. M. Janssen was of course equally unsuccessful. Though the darkness was almost appalling as it rapidly increased up to the moment of totality, still the scene was deprived of a large part of its impressiveness by the dense mantle of cloud which concealed nearly the whole heavens.

SOCIETIES AND ACADEMIES

London

Chemical Society, December 15.—Prof. Frankland, F.R.S., Vice-president, in the chair.—The following gentlemen were elected Fellows:—P. T. Atkinson, R. Koma, J. F. Stark. Mr. Perkin, F.R.S., read a paper "On some new Derivations of Coumarin." The author succeeded in obtaining the following new bodies:—

Dibromide of Coumarin	$C_9H_6O_2 . Br_2$
Dichloride of Coumarin	$C_9H_6O_2 . Cl_2$
α Bromocoumarin	$C_9H_5BrO_2$
β ,, ,, ...	,,
α Chlorocoumarin	$C_9H_5ClO_2$
β ,, ,, ...	,,
α Dibromocoumarin	$C_9H_4Br_2O_2$
β ,, ,, ...	,,
Tetrachlorocoumarin	$C_9H_2Cl_4O_2$
Coumarilic acid	$C_9H_6O_3$
Bromocoumaric acid	$C_9H_5BrO_3$
Sulphocoumaric acid	$C_9H_6O_2 . SO_3$
Disulphocoumaric acid	$C_9H_6O_2 . 2SO_3$

Dibromide of Coumarin.—A solution of coumarin in carbon disulphide is mixed with a similar solution of bromine, and the mixture, after leaving it to stand for twelve hours, allowed to evaporate spontaneously. When dibromide of coumarin is treated with an alcoholic solution of potassic iodide it becomes brown, and on evaporation deposits needles apparently consisting of a mixture of iodine and coumarin crystals, α *Bromocoumarin.* A simple process for the preparation of Bromocoumarin is to decompose the dibromide of coumarin with alkalis, the following reaction taking place:—

$$\underbrace{C_9H_6O_2Br_2}_{\text{Dibromide of coumarin.}} + KHO = \underbrace{C_9H_5BrO_2}_{\text{Bromocoumarin.}} + KBr + H_2O$$

α Bromocoumarin, when left in contact with cold alcoholic ammonia, decomposes with formation of ammonic bromide, and a non-crystalline sticky mass easy soluble in water. Heated with potassic hydrate it yields potassic bromide and a new acid. α *Dibromocoumarin.*—At a previous occasion Mr Perkin prepared this body by heating in a sealed tube to 140° C. a mixture of one part of coumarin, two parts of bromine, and four or five parts of disulphide of carbon. He since found, however, that this process is greatly improved by the addition of iodine to the mixture, as it is then only necessary to heat the sealed tube for four or five hours in a bath of salt and water to complete the reaction. The fusing point of this substance is 183° C. and not 174° C. as had been previously given. β *Bromocoumarin.*—The hydride of sodium bromosalicyl when submitted to the action of acetic anhydride, yields a quantity of hydride of bromosalicyl and a body which, when crystallised from alcohol, yields colourless flat prisms, the analysis of which showed it to be monobromocoumarin, $C_9H_5BrO_2$. It greatly differs in properties from the bromocoumarin previously described, its fusing point being 160° C., or 50° higher, and when boiled with alcoholic or aqueous potassic hydrate it does not decompose with formation of potassic bromide, but simply dissolves like ordinary coumarin. β *Dibromocoumarin.*—On treating the hydride of sodium *di*bromosalicyl with acetic anhydrate in exactly the same manner as for the preparation of β bromocoumarin, a beautifully crystalline product is obtained of the composition $C_9\ H_4\ Br_2\ O_2$. It is not the same body as that obtained by acting on coumarin with bromine and iodine. It fuses at 176° C., and is not decomposed by boiling with a solution of potassic hydrate. Mr. Perkin has, therefore, designated it as β dibromocoumarin. *Dichloride of coumarin.*—A solution of coumarin in chloroform absorbs chlorine gas, only minute quantities of hydrochloric acid being formed. On allowing the solution to evaporate spontaneously, after the chlorine has been passed through it for an hour or two, a syrupy product is obtained very like new honey. This is the dichloride of coumarin. From its products of decomposition, there can be no doubt that it possesses the formula—

$$C_9\ H_6\ O_2\ Cl_2$$

Chlorocoumarin.—A mixture of one part of coumarin and three parts of pentachloride of phosphorus, when mixed and heated in a retort placed in an oil bath, slowly react upon each other as the temperature rises, and when the oil has reached about 200 C. the product becomes a dark brown liquid. During this reaction, a volatile liquid consisting chiefly of terchloride of phosphorus distils over. The contents of the retort after treatment with water, becomes a pasty mass of crystals, which is first purified by distillation, and then by several crystallisations from alcohol. Its analysis gave the formula $C_9\ H_5\ Cl\ O_2$. It fuses at 122°—123° C., and, when heated, possesses an agreeable aromatic odour. *Tetrachlorocoumarin.*—Chlorine gas when passed through a solution of coumarin and iodine in tetrachloride of carbon is rapidly absorbed, hydrochloric acid being evolved. If the gas be passed for two or three hours a quantity of a reddish body separates; on evaporating the product so as to separate the tetrachloride of carbon an oily residue is obtained, the red substance having fused with the impurities. On mixing this with alcohol, it soon becomes a white paste. On pressing this in a small linen bag, a white product is obtained which is further purified by being several times crystallised from spirit. The numbers of the analysis lead to the formula—

$$C_9\ {}_2H\ Cl_4\ O_2$$

It fuses at 144°—145° C. Bromocoumarin, when boiled with a solution of potassic hydrate, decomposes, yielding potassic bromide and the salt of a new acid, which has the formula $C_9\ H_6\ O_3$. Mr. Perkin proposes to call it *Coumarilic* acid. It fuses at 192°—193° C., distils with partial decomposition, but sublimes undecomposed when gently heated. It is monobasic, and forms well defined salts with the alkalis, the alkaline earths, lead, silver, mercury, and iron. *Bromocoumarilic acid.*—It is prepared like the above, but substituting α dibromocoumarin for bromocoumarin. It possesses the formula $C_9\ H_5\ Br\ O_3$, and fuses at 250° C. *Sulphocoumaric acid.*—It is obtained on digesting a mixture of about one part of coumarin and five parts of fuming sulphuric acid in the water bath for an hour or two. From the analysis of its salts, the formula of this acid when anhydrous is $C_9\ H_6\ O_2\ SO_3$. Mr. Perkin has prepared ammonic, potassic, sodic, baric, and strontic sulphocoumarinates. *Disulphocoumaric acid.*—On heating a mixture of about 8 parts of fuming sulphuric acid and 1 part of coumarin to a temperature of 150° or 160° C. for an hour or two, the produced will contain two sulphoacids, viz., sulphocoumaric acid and disulphocoumaric acid. Its barium salt has the formula—

$$C_9\ H_4\ O_2\ Ba''\ 2\ SO_3.$$

—The next communication was by Dr. Debus. "On the formula of glyoxylic acid," Dr. Debus showed that this acid ought to be written $C_2\ H_2\ O_3$ and not $C_2\ H_4\ O_4$. He considers it in reality to be the aldehyde of oxalic acid. Among other reasons for this view he quoted its behaviour towards the bisulphites. Dr. Odling was of the same opinion. He saw the aldehydic character of glyoxylic acid in its property of combining with one atom of water or of ammonia, or ethylic chloride, &c. Mr. Perkin defended the formula $C_2\ H_4\ O_4$, quoting among other evidences for the correctness of his views, the behaviour of glyoxylic acid when treated with phosphoric pentabromide; instead of losing water and being converted into CO, it takes up three atoms of bromine.

TAUNTON

Somersetshire Archæological and Natural History Society, December 12.—W. E. Surtees, president, in the chair. In a paper by Mr. Cecil Smith on some rare birds found in the immediate neighbourhood of Taunton, a few observations were made on the following birds, specimens of all of which were produced. The first mentioned was the Pied Flycatcher, which had been killed in an orchard near French Weir, close by the town. Though rare in this and other southern and western counties, it was much more common in more northern counties, especially in the Lake district, where it was a summer visitant, remaining from April to November—it had, however, been taken as late as the middle of October at the Scilly Islands, when on its southern migration. The next bird mentioned was White's Thrush, of which four, or at most five, British specimens had been recorded. The specimen produced, which brought this bird within the limits to which Mr. Smith's paper was confined, had been killed at Hestercombe Wood, in January 1870; it was shot at by mistake for a woodcock. Of this bird it was observed that although it might be difficult to account for its presence in England, or even in Europe, there could be no doubt as to its identity, as this and other British killed specimens did not differ in the slightest degree from those brought over from Japan and the East. On the difficulty of accounting for its presence in England, Mr. Smith observed that the journey performed being almost entirely over land, the reason given for the appearance of many, especially of American birds on our shores, that being driven out of their usual migratory course, and out to sea by strong gales, they found no place of rest before reaching our shores, was not applicable. Neither would the supposition that it had got mixed up with flocks of other perhaps nearly allied species on what had been a common breeding ground, and accompanied them, be applicable. Still less would the theory hinted at in Yarrell that the occasional appearance of these Eastern birds in Europe is not so very strange, since as many as 114 species are enumerated by Temminck as common to Europe and Japan; but of these 114 species the great majority are inhabitants of both countries, and not wanderers from one to the other. One instance, the almost universally distributed Turnstone, was taken as an example, which, instead of wandering to such an enormous extent, appeared to be equally content, whether on the muddy shores of Somerset or at the Cape of Good Hope or in Japan. Perhaps, after all, the appearances of White's Thrush were to be attributed to a truant and vagrant disposition in the bird itself, which might lead it far from his own home. Probably the habits of the bird contributed slightly to its rarity in Europe, as it appeared to keep much out of sight in woods and plantations, and it had consequently, as in the present instance, been shot by mistake for a woodcock. The next bird mentioned was Tithy's Redstart, which was considered worthy of notice as having occurred so close to the town as Gulmington-lane. The difference between this bird and our summer visitant, the common redstart, was pointed out, and specimens of each shown. The peculiarity of this bird being a winter rather than a summer visitor to these islands, was remarked on especially, as it is a regular summer visitor to the middle and northern parts of Europe. Also its choice of localities, namely, rough, rocky situations, such as the Parson and Clerk rock at Teignmouth (at which place Mr. Smith had several times seen it in the month of November), in which it differed much from the common redstart, which preferred gardens, orchards, and hedgerows. The difference of the eggs was also remarked upon, those of the present species being white instead of the well-known blue of the common redstart. The occurrence of one specimen of the Sevin Finch, within the town of Taunton itself, brought this bird within the range of the paper, Mr. Smith observing that in the Birds of Somerset he had thrown some doubt upon this specimen, supposing it might be an escape, the time of year at which it was killed, the end of January or beginning of February, more than the rareness of the bird itself, leading to this doubt; he felt, however, bound to admit that there did not appear about the bird itself any signs of its having been in confinement. The other British specimens appear to have occurred in the summer between April and October, as might be supposed from its being an inhabitant of the south of Europe, and growing scarcer as we get farther north. The similarity to the Siskin was also mentioned, and specimens of this bird produced for the purpose of comparison, the difference in the shape of the beak being pointed out as the most reliable distinction, especially by candle light, which considerably increased the difficulty of distinguishing the colours. The Little Bittern and Baillon's Crake were also mentioned, and a specimen of each produced, both having been killed nearly in the same place, some rushy pools by the side of the river in Priory Fields. Attention was called to the similarity between the Little Bittern and its big relation, in the absence of feathers at the back of the neck. Mr. Smith added that he had seen by chance, in the shop of Mr. Petherick, the bird stuffer, a specimen of the Woodsandpiper, which had been killed by Mr. Petherick himself, on the 9th of May last, as near as Cheddar, which would bring it quite within range for mention in the paper

MANCHESTER

Literary and Philosophical Society, November 29.—R. Angus Smith, Ph.D., F.R.S., vice-president, in the chair. Mr. R. D. Darbishire, F.G.S., exhibited a series of palæolithic instruments from the valley of the Little Ouse, and explained (after Mr. J. W. Flower, Q. J. Geolog. Soc. xxv. 449) the general features of the district and the deposit of the beds and the implements.—Mr. W. Boyd Dawkins, F.R.S., indicated the age of these deposits as related to the period of the existence of *Elephas primigenius* in the district of the south-east of England and the adjoining portions of the bed of the German Ocean and the north-west portions of France.—"The Tails of Comets, the Solar Corona, and the Aurora considered as Electric Phenomena," by Prof. Osborne Reynolds, M.A. Although the tails of comets are usually assumed to be material appendages which accompany these bodies in their flight through the heavens—and the appearance they present certainly warrants such an assumption—yet this is not the only way in which these tails may be accounted for. They may be simply an effect produced by the comet on the material through which it is passing, an effect analogous to that which we sometimes see produced by a very small insect on the surface of still water. We see a dark spot, and on looking closer we find a small fly or moth flapping its wings and creating a disturbance which was visible before the insect which produces it. There is nothing else that we can conceive their tails to be, so that they must be one or other of these two things: either (1) material appendages of the nucleus, whether the material be limited to the illuminated tail or surround the comet on all sides; (2) matter which exists independently of the comet, and on which the comet exerts such a physical influence as to render it visible. There can be no doubt that if these tails are matter moving with the comet, this matter must be endowed with properties such as we not only have no experience of, but of which we can form no conception. This alone would seem a sufficient reason for rejecting the first hypothesis. Moreover, on the second hypothesis there is no difficulty in the immense velocity with which these tails are projected from the head or whirled round when the comet is in perihelio. For to take the "negative shadow" as an illustration, here we should have a velocity of projection equal to that of light, and the only effect of the whirling would be a slight lagging in the extremity of the tail, causing curvature similar to that which actually exists. And whatever the action may be, if its velocity of emission or transmission be sufficiently great, this effect will be the same; but whether this hypothesis is to be rejected because involving assumptions beyond conception or contrary to experience, must depend on the answers to the following question: Do we know, or can we conceive, any physical state into which any substance which can be conceived to occupy the space traversed by comets could possibly be brought so as to make it present the appearance exhibited by comets? Now I think the answer must be in the affirmative, and that we may leave out the terms conceive and conceivable. For electricity is a well-known state, and gases are well-known substances; and when electricity, under certain conditions, as in Dr. Geissler's tubes, is made to traverse exceedingly rare gas, the appearance produced is similar to that of the comets' tails; the rarer this gas is, the more susceptible is it of such a state, and so far as we know there is no limit to the extent of gas that may be so illuminated. Hence we may suppose the exciting cause to be electricity, and the material on which it acts and which fills space to have the same properties as those possessed by gas. What is more, we can conceive the sun to be in such a condition as to produce that influence on this electricity which should cause the tail to occupy the direction it does. For such an electric discharge will be powerfully repelled by any body charged with similar electricity in its neighbourhood. The electricity would be discharged by the comets on account of some influence which the sun may have on them, such an influence being well within the limits of our conception. The appearances of the comet in detail, such as the emission of jets of light towards the sun and the form of the illuminated envelope, are all such as would necessarily accompany such an electrical discharge. In fact, if the possibility of such a discharge is admitted, I believe it will explain all the phenomena of comets. As to the possibility, or even the probability of such a discharge, I think it may be established on very good grounds. The tails of comets may or may not be one with their heads; but whichever is the case, it is certain that the difference in the appearance of comets and of planets indicates some essential difference either in the materials of which these bodies are respectively composed, or else in the conditions under which their materials exist. Now from the motion of comets we know that their heads follow the same laws of motion and gravitation as all other matter, and therefore we have good evidence, so far as it goes, that comets and planets are similarly constituted as regards materials. And since the appearance of a comet changes very much as it passes round the sun, any assumptions with regard to the material of comets, in order to account for their difference from planets, could not account for the variety of appearance the same comet presents at different times. On the other hand, the conditions of comets and planets must necessarily be very different, from the extreme difference in the shapes of the orbits they describe. Each planet remains nearly at a constant distance from the sun (whatever that distance may be), so that the heat or any physical effect the sun may have upon it will also be constant; on the comets its action must change rapidly from time to time, particularly when the comet is in certain parts of its orbit. Hence we may say that the temperature and general physical condition of planets is nearly constant, and that of comets for the most part continually varying. From these reasons it seems to me not only possible, but probable, that these strange visitors to our system are clothed in electrical garments with which the regular inhabitants are unacquainted. The electricity must after all depend on the composition of the comet, for known substances do not all show the same electrical properties. Hence by assuming comets to be composed of various materials, we have a source to attribute the different appearances presented by the different individuals. To the same source we may attribute the irregularity in the direction of their tails and the lateral streamers they occasionally send out. Secondly, I think this electrical hypothesis is supported by the to me seeming analogy between comets, the corona, and the aurora; an analogy which suggests that they must all be due to the same cause. They may be all described as streams of light or streamers, having their starting point more or less undefined, and traversing spaces of such extent and with such velocities as entirely to preclude the possibility of their being material in any sense of that word with which we are acquainted. The aurora has long been considered as an electric phenomenon, and recently the same effect has been produced by the discharge of electricity of very great intensity through a very rare gas, there being no limit to the space which it will thus traverse. This being so, why should not the tails of comets and the corona also be electric phenomena? Their appearance and behaviour correspond exactly with those of the aurora, and there is surely nothing very difficult in imagining the sun which is the source of so much heat being also the source of some electricity. Neither will there appear anything wonderful in the electricity of comets when we consider that of the earth. We must not look on our inability to explain the cause of such an electric discharge as fatal to its existence, for we cannot any more explain the existence of the electricity which causes the aurora. If we cannot explain from whence these electricities come, we can at least show that the conditions which are most favourable to the development of the aurora exist in much greater force on the comets than they do on the earth. The greatest development of the aurora borealis takes place at the equinoxes. There is a cessation in summer, and another in winter. Now, the equinoxes are the times when the action of the sun on our northern hemisphere is changing most rapidly. Hence the condition favourable for the aurora is change in the action of the sun. The same thing is pointed out by the diurnal variation in the electricity of the atmosphere. Now, as has been already shown, the change in temperature on the comets is incomparably greater than it is on the earth, and its variation corresponds with the variation in the splendour of the comet. Angström has also shown that the light from the aurora, the corona, and the zodiacal light, are all of the same character, or all give the same bright lines when viewed through the spectroscope, and that these lines correspond to the light from no known substance. This indicates that whatever this light may be, the incandescent material is the same in all cases; or may we not assume that it is the medium which fills space that is illuminated by the electric discharges? This would be supported by the fact that the light from the heads of two small comets indicated carbon, whereas that from the tails only gave a faint continuous spectrum. For an electric discharge would first illuminate the atmosphere of the comet, or even carry some of the solid material off in a state of vapour, and then pass off to the surrounding medium. Thus while the spectrum from the head would be that of cometary matter, the tail would be due to the incandescent ether. I would here suggest that gas, when rendered incandescent by electricity, may reflect light—it will certainly cast a shadow from the electric light—and if this be the case, part of the light from comets' tails may after all be reflected sunlight. At any rate, it is certain that the appearance of streamers, the rapidity of change and emission, the perfect transparency and the wave-like fluctuations which belong to these phenomena, are all exhibited by the electric brush; in fact, the electric brush will explain all these appearances which have defied all attempts at explanation on a material hypothesis. I have only to add that the main assumption involved in the electric theory is that space is occupied by matter having similar electrical properties to those of gas; and I would ask, is it not more rational to make such an assumption than it is to attribute unknown and inconceivable properties to cometary matter? Theories, even if founded only on rational speculation, often, I believe, prove very useful, inasmuch as they afford observers a definite purpose in their observations—something to look for, something to establish or to refute; and I publish these speculations of mine at this particular moment in the hope that they may perchance serve such a purpose.

PHILADELPHIA

American Philosophical Society, October 7.—Dr. Binton made some observations on a Mazahc theological work and grammar, indicating probable resemblances between the language of that nation and that of the Aztecs. He also described a grammar of the Moska nation of New Granada, prepared by Father Lugo.—J. A. Macneil described the ruins and other remains of the ancient nations, which he had discovered during several expeditions in Nicaragua, Costa Rica, Chiriqui, and Chiapas. He made especial reference to an extensive series of ruins he had discovered near the boundaries of Chiriqui and Costa Rica. One of the buildings was 600 feet in length, and 25 to 30 feet elevation. Among other sculptures he observed a well-executed stone alligator of large size.—Prof. Cope exhibited the remains of a new cretaceous tortoise, of the genus *Adocus* Cope, to be called *A. syntheticus*. He explained that he had been able to establish more fully the characters of the genus *Adocus*; that it was found to possess an intergular shield as in the Pleurodira, but had not the sutural union of the inferior pelvic elements with the plastron of that type. He said that these characters had been heretofore known as correlatives from the cretaceous period to the present day, and that this genus presented us with the first exception to the rule. The genus was therefore regarded as a generalised type, and to be elevated to the rank of a family. Prof. Cope exhibited a metatarsus of *Taelaps aquilunguis*, the first known, and said it proved the distinctness of those elements from each other in that type, and their slenderness, taken collectively. The specimen was an external one, without trace of a rudimental one outside of it; that its measurement, 16 inches, was indicative of a length of 18 inches to the median metatarsus, a length he had already assigned to it on theoretical grounds. Prof. Cope read a paper entitled, "Contribution to the Ichthyology of the lesser Antilles." Two new genera were described in it, viz., *Eleutheractis* and *Cryptotomus*.

Academy of Natural Sciences, November 8.—Prof. Leidy characterised three species of extinct turtles, obtained by Prof. Hayden's party from the tertiary deposits of Wyoming. Two were named *Emys Haydeni* and *E. Jeanesi*. The third, partaking of characters of the genera *Chelydra* and *Dermatemys*, was named *Baena arenosa*. A lacertian, as large as the largest of our living Iguanas, was characterised from the greater part of the bones of a skeleton imbedded in a rock of tertiary age, from Wyoming. The vertebræ have the characteristic ball and socket-joint to the bodies, but they are devoid of the zygosphene and zygantrum. The teeth are compressed conical, slightly curved, sharp-pointed, and trenchant. The remains were referred to a species with the name of *Saniwa ensidens*. The names *Baena* and *Saniwa*, according to Prof. Hayden, are those given to the turtle and lizard by one of the aboriginal tribes of the Upper Missouri.

VIENNA

I. R. Geological Institute, December 6.—Dr. Laube presented a memoir on "the Echinidæ of the Upper Tertiary Deposits in the Austro-Hungarian Empire," which will be printed in the fifth volume of the Memoirs of the Institute. The total number of distinct species is 37, six of which belong to the lower, and 31 to the upper part of the Mediterranean formation.—M. F. Foetterle "on the Sarmatic formation in the Bukowina and Northern Moldavia." It occupies an enormous space in both countries, and is easily divided in two members, an upper formed of yellow sand and sandstone, and a lower which consists of blue clay. Both contain fossils in abundance. The clay is everywhere permeated with very thin veins and layers of fine sand, which give free access to water, and thus cause the greatest difficulties for the railroad between Czernowitz and Jassy, which for long tracts passes over the clay, and is damaged by very long continued falls of rain.—M. Th. Fuchs reported on the Fauna of the Congeria-beds of Tihany and Kup in Hungary.—M. Ch. v. Hauer communicated the analysis of fire-proof clay of Fohnsdorf (Styria) which forms there a layer 9 feet thick in the browncoal basin. It consists of a hydrosilicate of alumina and magnesia, and belongs to the so-called soap-stones.—M. E. Tietze gave notice of the discovery of fossiliferous beds belonging to the brown Jura at Boletin, in Servia, and of neocomian and turonian beds in north-eastern Servia.—M. M. Neumayr presented a memoir on the jurassic flint-limestones of the Carpathians.—M. D. Stur exhibited a magnificent collection of eocene fossils from the environs of Vicenza, which had been purchased for the Museum of the Institute.

DIARY

FRIDAY, JANUARY 6.

GEOLOGISTS' ASSOCIATION, at 8.

SATURDAY, JANUARY 7.

ROYAL INSTITUTION, at 3.—Burning and Unburning: Prof. Odling (juvenile lectures).

SUNDAY, JANUARY 8.

SUNDAY LECTURE SOCIETY, at 3.30.—Malta and the Maltese, with a visit to St. Paul's Bay: Dr. Carpenter.

MONDAY, JANUARY 9.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.

TUESDAY, JANUARY 10.

PHOTOGRAPHIC SOCIETY, at 8.

ETHNOLOGICAL SOCIETY, at 8.—On the Prehistoric Remains in Brittany: Lieut. S. P. Oliver, R.A.—Exhibition of Stone Implements from Queen Charlotte's Island: Dr. Hocker, C.B.—On a Cairn near Cefn, St. Asaph: Rev. D. R. Thomas, M.A., and Mr. T. McK. Hughes, M.A.

WEDNESDAY, JANUARY 11.

GEOLOGICAL SOCIETY, at 8.—On the older Metamorphic Rocks and Granite of Banffshire: Mr. T. F. Jamieson, F.G.S.—On the Connection of Volcanic action with Changes of Level: Mr. J. J. Murphy, F.G.S.—On the Geology of the neighbourhood of Malaga: Don M. de Orueba.

ROYAL MICROSCOPICAL SOCIETY, at 8.—On the Anatomy of *Ascaris lumbricoides*: Mr. B. T. Lowne, M.R.C.S.—On the use of Colloid Silica in preparing Crystals for the Polariscope: Mr. H. J. Slack.

THURSDAY, JANUARY 12.

ROYAL, at 8.30.

SOCIETY OF ANTIQUARIES, at 8.30.

LONDON MATHEMATICAL SOCIETY, at 8.—On Systems of Tangents to Plane Cubic and Quartic Curves: Mr. J. J. Walker.—On the Order and Singularities of the Parallel of an Algebraical Curve: Mr. S. Roberts.

THURSDAY, JANUARY 12, 1871

THE NEW HOSPITAL OF ST. THOMAS

FEW more marvellous creations of constructive art have burst in rapidly maturing beauty upon the eye than the noble *vis-à-vis* which now faces the Palace of Westminster, and looks across the Thames at it from the opposite stretch of Embankment, rendering the site which is centred by Mr. Page's graceful bridge, one of the most remarkable that is to be found in the chief cities of the world. The Hospital may possibly be held to be subordinate to the Palace in dignity and grandeur of external form; but in two particulars it must be admitted to be in no way inferior to its rival. It is dedicated to a purpose of highest and purest beneficence, the alleviation of human suffering, and to unceasing conflict with one of the most potent of the powers of physical evil; and it is a *chef-d'œuvre* of perfection and completeness for the accomplishment of the end to which it is destined. Within thirty-one short months this vast building has been so far advanced under the hands of a staff of nearly 900 workmen, that it is now quite possible to take a comprehensive view of the purpose and plan of its designers, and fairly to contemplate in its most advanced form the idea of what a public Hospital should be in these days of scientific development and conquest.

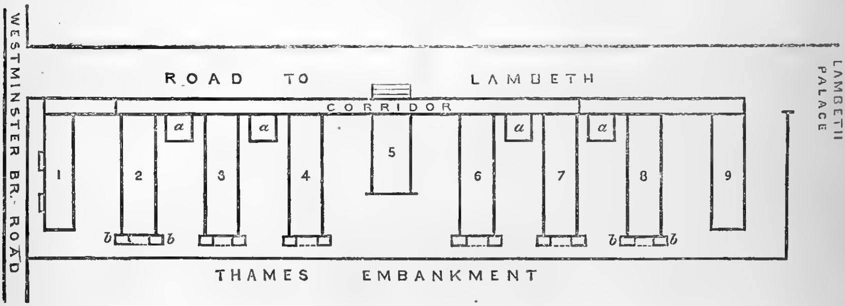
It is a matter of notoriety, that after a period of perplexity and doubt,—during which it seemed at least problematical whether the old Hospital of Edward VI., which had been ejected from its primary home near the southern end of London Bridge by the remorseless demands for increased railway access on that side of the metropolis might not be scattered into disjointed fragments for want of a sufficiently spacious central site, where its functions might be efficiently and conveniently resumed after the old fashion and upon the old scale,—it has been found practicable to give it a new habitation in Lambeth, in a position in no sense inferior in promise of direct usefulness to the one it previously occupied in the borough of Southwark, and in many particulars with a marked and unquestionable accession of advantages in the change. In accomplishing this task, it was wisely determined, after due deliberation upon all the interests involved, so to use the great opportunity as to show to the world what is required by the present conditions of sanitary and medical science in a Hospital erected for the study and cure of disease and casual injury. This, of course, could only be accomplished at some cost in the matter of money and space. But it was held that a very considerable measure of compensation might be at once effected by the adoption of very perfect organisation and very complete mechanical contrivance; and that beyond this any money outlay which establishes a model of perfection in Hospital construction and arrangements, must be admitted to be a wise and sound investment for the community on other grounds.

The most casual observer of the external aspects of this vast pile of building will at once perceive that the fundamental idea of the plan is the breaking up of the structure into a series of subordinate blocks, which must allow of the most thorough and ready permeation of fresh air to every part of the inhabited interior. The *beau ideal* of the ward of a Hospital is that it shall be a spacious room, constructed with due regard to the number of inmates it is allowed to accommodate, open on all sides to the fresh blasts of Heaven. The problem in this individual case has been to determine how several hundreds of inmates can be lodged in a building placed in a densely inhabited part of a great city, without violence being done to this fundamental necessity. In the new Hospital of St. Thomas nine distinct blocks of buildings have been spread along the immediate Embankment of the river, from the end of the bridge at Westminster to the Archbishop's Palace at Lambeth, in such a way that they have the open space overlooking the broad channel of the Thames at one side, and a roomy thoroughfare connecting the Westminster Bridge Road with Lambeth at the other. These blocks are of elongated form, their longest dimensions lying transversely to the course of the river, so that their ends look down upon the stream; their sides being severed by intermediate areas of clear space. Each block, in the main, is simply a stack of long single wards with windows at each side, placed one upon the other. But these wards are bulbous, or enlarged, at the river ends, for the sake of architectural effect, and for purposes of convenience which will be hereafter mentioned. But for almost the entire extent of their longest dimensions they are purely single long rooms pierced by spacious windows at both sides. On the ends opposite to the river these blocks are, in the lower flats, connected together by corridors contrived for the purpose of interior communication; but, throughout the upper flats the isolation of the blocks, and, therefore, the permeability to free air, is complete. Further reference will have presently to be made to the admirable way in which the work of necessary communication has been managed.

In broad outline the plan of the arrangement is, therefore, that which is presented to the eye in the sketch on the following page.

With respect to these blocks, it may be stated that No. 5 is the Central Hall, with entrance from the Lambeth Road, and the Chapel. No. 1 is the administrative block, consisting of the Governor's rooms and the Treasurer's residence, and No. 9 is the Museum and Medical School. The blocks 2, 3, 4, and 6, 7, 8, are, therefore, the Hospital proper. Each of these blocks consists of four flats, with an attic story above, and a basement story beneath. But the first floor in block 4 is appropriated to the accommodation of the linen and to the matron's use; and the corresponding floor in block 6 is absorbed by the kitchen and cooking apparatus. Block 8 is the compartment reserved apart for contagious and infectious diseases, and is differently arranged to the other Hospital blocks. There are therefore four large Hospital wards in blocks 2, 3, and 7, and three large Hospital wards in blocks 4 and 6. Each of these large wards in the three upper flats will accommodate 28 beds. The first floor wards in blocks 2, 3, and 7 are necessarily of somewhat smaller size, and are designed for 20 beds. All the patients' wards taken together, including those of block 8, and sundry small private wards scattered about the building, afford ample accommodation for six hundred indoor patients.

The principal channel of communication between the several blocks of the building is one long corridor on the ground flat or floor. This corridor runs the entire length from the administrative block (No. 1) to the block for contagious diseases (No. 8). But the portions of the corridor which lie between blocks 1 and 2, and between blocks 7 and 8, take the form of an open colonnade. For the rest of the distance, it is intrinsically an internal passage. The open, or colonnade, portion which leads to block 8, the assigned seat of infectious disorders, is carefully cut off from the rest of the corridor by closed glass doors, so that all contamination of the other blocks of the building by the infected air is simply impossible. The open air-space which intervenes is ample for the neutralisation and destruction of atmospheric infection of any kind. The marvellous extent of space covered by this hospital is perhaps best estimated by stating the actual length of this corridor. The continuous length of the spacious passage is 916 feet from end to end. A very pleasant and convenient communication between the several blocks is effected on the second floor by a casemented passage, which runs along the main corridor. The communication for the third floor is along the open flat roof of this casemented passage; and above this there is no communication at all between the blocks. The effect of the light and airy outlook, giving the impression of altogether unrestricted lightness and freshness, which is encountered in passing along these higher passages of communication, is very charming and agreeable. There is scarcely anything in the arrangements of the buildings which is more striking and pleasant to an observer upon a first visit. The open passage at the top is guarded by a balustrade, which is very profusely ornamented by large urns made of artificial stone; a material which has been largely employed in the ornamental parts of the structure. This compound, which is a special patent, is formed of dissolved flint mingled with sand, the material being then saturated with silicate of potash under exhaustion or pressure. It is expected that this artificial stone will possess very enduring qualities, but from the present aspect of these urns the writer of these lines inclines to think that the material yet needs further evidence of endurance and success before it can be held to have established the character at which it aims.



In addition to these corridors of communication, there is a still longer passage in the basement, extending quite from the administrative block to the Museum and Schools at the farther end of the structure, and giving immediate access to the department for washing linen, and to the Anatomical Schools and mortuary receptacles which lie beyond under the shadow of the old walls of Lambeth. There is also a sunken but open-air way running from end to end of the building immediately within the parapet trenching upon the river-embankment, which gives still further facility for the transport of heavy material. This channel of communication is very ingeniously and completely masked from observation both from the building itself and from the external space.

The important and interesting details relating to the arrangements which have been made within the large wards themselves to fit them for their beneficent work, must be reserved for another article.

R. J. M.

THE COLLECTION OF INVERTEBRATE ANIMALS IN THE FREE PUBLIC MUSEUM, LIVERPOOL

IN October 1861, when the Natural History collections presented to the town of Liverpool by the grandfather of the present Earl of Derby were removed from Duke Street to the building which they now occupy, the question arose, how should the museum be made as fully as possible to answer the requirements of the population by whom it was to be supported under the provisions of the Library and Museum Act.

The Curator, Mr. Moore, whose invaluable services are too well known to require further notice on my part, having on his hands, besides the duties of general superintendence, the re-arrangement of the extensive series of Mammalia and Birds, together with preparations for the reception of a similar series of Fishes and Reptiles, availed himself of my offer of assistance in obtaining and arranging a collection of Invertebrate animals, our stock of which at that time included little beyond some corals and a few very miscellaneous specimens.

The accommodation available for the proposed collection consisted of the central areas of a suite of five rooms

27 feet in breadth, the total length being 250 feet. Space was thus provided for eighteen table-cases, each 10 feet long, set transversely. One important point was therefore settled by the shape of the building. The series had to be conformed to a linear arrangement. In some respects this was a serious disadvantage. The classes of Invertebrate animals cannot well be represented in a single ascending or descending series. Probably it would not be possible on any symmetrical plan to indicate their proper positions relatively to each other; but some palpable incongruities might be avoided by the use of table-cases on a ground-plan, resembling in form a tuning-fork. The Protozoa, as the stem, pass naturally enough on one side by the Rotiferæ and their allies to the Annelida, Echinodermata, Crustacea, and Insecta; and on the other by the Cœlenterata to the Molluscoida and Mollusca; the greater size of the specimens forming the latter prong of the fork, compensating for the vastly more numerous species in the former. The importance of a suitable ground-plan for cases in Museums seems to be much underrated. When a class of students visit a museum frequently, the localities of cases containing special groups become indelibly impressed upon the memory. Why should not this be turned to good account?

In preparing the first scheme of the collection, it seemed to me essential that plain, and moderately simple, printed descriptions of the life history of the animals should accompany the specimens, but, as it was clearly impossible to describe every species, or even every genus, it became necessary to fix on some mode of associating in groups a number of species to which the descriptions might apply. Such divisions as "classes" and "orders" were manifestly too large; whilst "families" varied from a single genus, including a solitary species, to an army of more than a thousand genera, *e.g.* the Cerambycidæ and Curculionidæ in the Coleoptera. It was with some regret that the idea of attaching a readable sketch to each division of a given rank in recent systems of classification was relinquished, but it was found to be impracticable; and the life history sketch thus became the foundation of the system eventually adopted. Whether it might be a few species, or a genus, or a family, or an order, that seemed to afford suitable scope for a paragraph of readable and instructive matter, it was decided that such a group should be segregated, so as to form the unit of the series. Eventually, in order that the sketches, which it was proposed to print for the purpose on tablets, might all be in positions where they could conveniently be read, it was found to be expedient that each group, or unit, should occupy an equal space; and as the blocks on which the table-cases rested were to be fitted up with trays or drawers, twelve of which would occupy the table-case without loss of room, these trays or drawers were adapted as the receptacles and boundaries of the groups.

The drawers measured twenty-seven inches in length by sixteen inches in breadth, and their number in the eighteen table-cases, when completed, would be 216. Then arose the problem, how best to divide the twenty classes of Invertebrate animals into 216 groups, each of which should be capable of affording materials for a biological notice, such as might be read with interest by any intelligent visitor.

The entire plan of the table-cases, and the limits of most of the groups, were committed to writing before any considerable advance had been made in procuring specimens. In one respect this circumstance was found to be very advantageous—our *desiderata* were at once well-defined. It was an object that each of the groups should be illustrated by carefully selected specimens, and until this could be attained, other acquisitions need not be sought for. In making purchases, such an object steadily kept in view exercises a powerful influence against the seductive attractions of "great bargains," which often turn out to be great misfortunes to a Museum. Moreover, in accepting donations, it is sometimes convenient to be able to refer to a fixed plan. Where room is scanty, as in most Museums, nothing is more subversive of order, or more fatal to an instructive arrangement, than the gift of a collection, coupled with a stipulation that it must be displayed in some special way. It is far better to forego the possession even of a valuable series of specimens, than to sacrifice order for their sake.

The number of groups, 216, will, no doubt, appear to have been determined simply as a matter of convenience. To a certain extent this is true. After a careful reference to the best available authorities on each of the Invertebrate classes, in which much assistance was afforded me by the many valuable scientific works in the Free Public Library of Liverpool, and by the catalogues of the collections in the British Museum, it seemed probable that most of the prominent forms in all the classes might be exhibited in pairs, with their names attached in very legible type, in an area less than a thousand square feet; and that they might appropriately be disposed in 240 groups, occupying twenty table-cases. For these, the suite of five rooms above referred to would have been sufficient, but two large circular stoves occupied the room of two table-cases, and the groups had to be reduced to 216 in number, instead of 240, as in the original design.

For constant exhibition to the public, the series may perhaps be regarded as quite sufficiently extensive. Four table-cases contain the Protozoa and the Cœlenterata. Seven are given to the Molluscoida and Mollusca, in which department the collection includes representatives of about eleven hundred out of the thirteen hundred genera and sub-genera adopted by Messrs. H. and A. Adams in their work on "The Genera of recent Mollusca." Three cases are occupied by Echinodermata, Annelida, and Crustacea. This is by no means in proportion to the other parts of the series, and here it is that the want of the two absent table-cases is most felt. Four cases hold the Arachnida, Myriapoda, and Insecta, in which all the orders are fairly illustrated, except Strepsiptera. Stylops has not yet arrived—perhaps this may meet the eye of some friend who, for love, money, or specimens, may be willing to supply the deficiency.

It is hardly necessary for me to point out the difficulties and disadvantages which must attend an attempt to form a collection in which the whole of the Invertebrate classes are divided into a given number of equal groups. If all very distinct forms are to be exhibited, some groups must be heterogeneous in composition, but not necessarily very many. Such forms as Pycnogonum, Forficula, Siphonaria, Sagitta, Cydippe, &c., may have to appear as interlopers; but the printed tablet may explain the irregularity of their position, and render the disadvantage simply a negative one,—in such cases the plan cannot afford much help to the memory. On the other hand, the tray or drawer containing an entire group can, with the utmost facility, be moved, to be re-arranged, to illustrate a lecture, or to occupy a different position in the series.

In the present unsatisfactory condition of "classification," probably the only thoroughly scientific mode of conveying information respecting an assemblage of organic forms, is that adopted by Professor Huxley, Professor Rolleston, and others, of describing completely a single included species; but this method seems more suited for students than for a mixed company, such as have visited our institution since October 1861, during which period the admissions to the Liverpool Museum have exceeded four millions one hundred and sixty-two thousands. The mode of arrangement adopted within the groups will be described in a subsequent notice.

HENRY H. HIGGINS

UTILISATION OF SEWAGE

A Digest of Facts relating to the Treatment and Utilisation of Sewage. By W. H. Corfield, M.A., M.B. Oxon, Professor of Hygiene and Public Health at University College, London. Prepared for the Committee of the British Association. (London: Macmillan & Co. 1870.)

DR. CORFIELD, now the Professor of Hygiene and Public Health in University College, London, after having been a most distinguished student in the old University of Oxford, has put before the world in a well and large printed volume of something less than 300 pages, a clear, readable, and reliable *résumé* of the "Great Sewage Question." The labour which has been thus expended in lightening the labours of others can be adequately judged of by but few persons; but amongst those few may perhaps be reckoned individuals who, like the writer of this review, have for their sins or through their foolishness, been entrapped into serving on the drainage committees of Local Boards, and have felt themselves compelled, in the way of expiation, to purchase, if not to peruse, the hydra, or rather the medusa-brood of blue books which parliamentary commissions and privy council offices are so constantly giving off. Had Professor Corfield always given chapter and verse, page and paragraph, for his citations from the vast number of volumes to which we allude and he has referred, he would have put his claim to credit on the score of painstaking laboriousness more prominently before the eyes of his readers, though he might not thereby have made the reading of his work much the easier for them. As it stands, his book is eminently easy of comprehension, and we will, without further preface, say a few words as to the general outlines of the ground he professes to cover in it.

The first 103 of the 282 pages of which the book consists, are taken up by an account, which is partly archæological, and partly, we regret to say, as yet not so, of certain systems for dealing with refuse which all alike labour under an amenability to an objection which our author, like ourselves, would appear to judge to be fatal to them. This objection he thus states (pp. 59, 60)—"The question, in fact, to be solved would appear to be with all the methods which require hand and cart labour: how can the refuse matters be kept as long as possible without being positively dangerous to health? instead of, as it should be, how can they be got rid of as fast as possible? This consideration at once stamps all methods of removal by scavenging, and must of itself bind them to a false principle, and lead to their condemnation." They are rightly, we would suggest, called systems of Conservancy, professing, as they do, to *keep* something awhile, which it would be better to lose at once. This portion of the professor's book is closed with a quotation from the "First Report of the Rivers' Pollution Commissioners" relating to one of those methods which at the present moment would appear to enjoy a considerable popularity; and this quotation we will follow his example in reproducing, observing by the way that to the words "First Report of the Rivers' Pollution Commissioners," there should have been added the words, "appointed in 1868, published in 1870, p. 50," to save readers the trouble of referring to another Blue Book put out by another set of Commissioners appointed in 1865. The quotation is to the following effect:—"Add to those circumstances the enormous aggravation of all the difficulties of the plan, when not 50 but 5000 households have to be provided with the necessary appliances, and are induced to work them properly, and we can have no hesitation in pronouncing the dry earth system, if superior for institutions, villages, and camps, where personal or official regulations can be enforced, entirely unfitted to the circumstances of large towns."

With his fifth chapter, p. 104, Dr. Corfield begins the history of the particular sanitary apparatus which is known on the continent as the "*Cabinet Anglais*," and with the various modifications, applications, and bearings, agricultural and hygienic, of the means for the water carriage of refuse, the rest of the book is filled up. Prof. Corfield is something of a physicist and of a chemist, and, thirdly, of a biologist; and it is to be expected, and will be found, that he is not ignorant, firstly, that water-carriage is the cheapest of all modes of carriage; secondly, that ammoniacal gas is dissolved in, and most tenaciously held fast by when dissolved in, one-thousandth of its own volume of water; and that, thirdly, this same chemical element, "the valuable constituent of sewage *par excellence*," can, when thus carried to land bearing crops, be taken up by them and used by them in their synthesis of albuminates for us animals. The obvious corollary of these rudimentary truths is the acceptance of the principle of the disposal of sewage by irrigation, to the rejection, except under exceptional conditions, of all others; and this corollary our author thus states for us (p. 176), "All other systems than that of removal by water go upon the principle that it is not dangerous to leave excretal matters, either in a crude state (pail closets) or mixed with some absorbing or deodorising material (various other forms of closet) for a certain time in or about houses. The fundamental principle being obviously a wrong one, it is not to be wondered at that such systems continually fail. . . . The water carriage system, on the contrary, sends all the refuse matters at once to a distance in the cheapest manner possible by the mere action of gravity. . . . Figures are stubborn things to deal with, and the sanitary benefits already attained by this system are so astonishing that we have a right to demand from those who would supplant it, proof of much better results of some other method, and not mere doubtful probabilities." *

In this connection we must note the omission from this valuable digest of any mention of Mr. Baldwin Latham's newly-invented, most simple, and most efficacious machinery for straining off, or rather for dredging out, of the entire mass of the sewage of a town those more coarsely divided, which are also the most grossly offensive and the least useful, of excretory products, together with the floating non-excremental rubbish, such as corks and other "properties" of the complex compound in question. Prof. Corfield, as a disciple of the late Dr. Daubeny, to whose work he refers with a very proper reverence, is too good a botanist not to be aware how hurtful it is to the vital operations of plants, in disinfecting and rebuilding up decaying organic compounds, for them to have their leaves and stems besmeared over with adherent viscosity; this non-transpirable envelope being as really injurious to them as the sight of coherent masses of filth is æsthetically disgustful to us; and both these difficulties Mr. Latham's invention has removed. Croydon, we learn from the guide-books, is not inaccessible from London; and "possesses," to quote further from the same authorities, "many objects of interest for the intelligent visitor." We trust Dr. Corfield will follow the example of the health officer of Bombay, who, in a sanitary tour, the results of which are given us in the "Report of the Measures adopted for Sanitary Improvements in India, from June 1869 to June 1870," visited Croydon, and has reported (p. 232) most favourably upon the particular "object of interest" in question, and its successful coadaptation of the turbine of the dredging machine and of the Archimedean screw.

With a few disjointed remarks we will conclude our notice of this useful work. Dr. Corfield, like most men who can calculate, is an adherent of the "separate system" as regards the rainfall and the sewage proper. Mr. Menzies' name, however, has somehow or other slipped out of his pages (159, 160), where he treats of this improvement on the older plans for sewage. We feel ouselves bound in our rate-paying capacity, to say nothing of any other, to emphasise the name of the Windsor sanitarian, knowing how much his writings have saved us in brickwork.

It is half amusing, half melancholy, to have to note how preachers of Hygiene have, like preachers of higher things, to "become all things to all men, that by any means they may save some." If Dr. Buchanan (see p. 170) is quoted in one place as telling us in a single sentence what another sanitarian professes to tell us in a whole volume (*Der Einfluss der Wohnung auf die Sittlichkeit*), viz., "that the progress made by the inhabitants of certain towns inspected, in decency, cleanliness, self-respect, and morality, was at least as striking as the improvement in their health measured by the mortality returns;" we find at another the preacher of Hygiene (see p. 25) continually pointing out that sickness is the chief cause of the non-payment of rent, and appealing to witness after witness, who assure him in voices trembling with pathos, and in language worthy of such sentiment, that "rent is the *best got* from healthy houses."

Professor Corfield's book will, we doubt not, shortly appear in a second edition. In this second edition we shall hope to find a bibliography such as that which Varrentrapp has appended to his work "Ueber Entwässerung der Städte." In this bibliography we shall hope to find Pettenkofer's papers duly and chronologically catalogued, it being the bounden duty of all sanitarians to help in propelling the sphere of Munich Hygiene out of the penumbra in which it is at present into full sunlight. To his bibliography our author will do well to superadd an index, and in correlation with his index should be, from page to page of his text, references given to the pages of the memoirs he quotes. It is not everybody who possesses the often Brobdignagian Blue Books of sanitary commissioners; but those who do possess them like to have these references, and those who do not, will not be much harassed by their insertion. We have suggested the making of these additions to the end of this book; they will cost their writer much, and save his readers some trouble if carried out. We will suggest the making of an addition to the beginning of his book, and that in the shape of a motto which was suggested to ourselves by one of the first of living scholars as an appropriate one for the Thames Conservancy. It may be found some seventy lines short of the end of Hesiod's "Works and Days," and runs thus:—

> *Μηδέ ποτ᾽ ἐν προχοῇ ποταμῶν ἅλαδε προρεόντων*
> *Μηδ᾽ ἐπὶ κρηνάων οὐρεῖν, μάλα δ᾽ ἐξαλέασθαι,*
> *Μηδ᾽ ἐναποψύχειν·* * *τὸ γὰρ οὔτοι λώϊόν ἐστιν.*

OUR BOOK SHELF

Choice Stove and Greenhouse Plants. Vol. II. By B. S. Williams. (London: Williams, 1870.)

PURELY horticultural works are somewhat out of the range of this journal, but in the present book, besides the usual practical cultural instructions, the author has thrown in much valuable information on the native habitats and uses of the plants enumerated. The palms, being a large order and such general favourites, occupy a large portion of the book, and the following may be taken as an example of its style:—

"*Borassus flabelliformis.* Of this noble palm, a native poem, in describing its beneficial properties, records nearly one thousand uses to which its products may be applied. It is a gigantic tree, reaching eighty feet or more in height, and two feet in diameter; the leaves are nearly circular, and plaited like a partially open fan, and have about seventy ribs, which radiate from a common centre. As young plants (which are the only specimens of this genus existing in this country), they are exceedingly handsome, but they are very rare and of very slow growth. The sap produces a very intoxicating toddy, from which sugar of superior quality is made and imported into this country, while its leaves are used for making hats, baskets and mats, umbrellas, fans, bags, and also in the manufacture of a very nice kind of matting for floors, as well as for thatching, &c. It is found principally near the sea, on low-lying sandy tracts, widely distributed throughout Asia." An excellent but very much condensed chapter on "Palms and their Uses" is likewise appended.

* See further, p. 226 to p. 282, in which pages the detailed facts are given as verifiable at many places, from Edinburgh, where irrigation has been practised for a couple of centuries, to Milan, and in which we are told that the famous chemist, Dumas, whilst inspecting the well-known Barking Farm, exclaimed, "oui, l'eau doit être la charette de l'engrais."

* The word ἐναποψύχειν is not a common one. Its meaning is well given by Mr. Simon in his last Report (Twelfth Privy Council, Medical Department, 1870), p. 16, *à propos* of the habits of the "polite natives" of Wakefield.

We avail ourselves of the opportunity of noticing this book, because, while it is intended to circulate chiefly amongst gardeners, both professional and amateur, it seeks to convey such information on the real value of the plants, which, we think, should in all cases be a point in a gardener's education. J. R. J.

A Cyclopædia of Quantitative Chemical Analysis. By Frank H. Storer, A.M., Professor of General and Analytical Chemistry in the Massachussetts Institute of Technology. Part I., pp. 112. (Boston and Cambridge: Lever, Francis, and Co. London: E. and F. N. Spon, Charing Cross, 1870).

THIS book is a compilation of all the known methods of quantitative analysis. The processes and necessary apparatus are minutely detailed, the descriptions being reproduced from the various handbooks of chemistry and from the original memoirs. The labour entailed by such a work must necessarily have been very great, and its value is much increased by the numerous references to the original descriptions of the processes. This part extends as far as the article on carbonate of silver, from which some notion of the extent of the whole work may be obtained. The principles on which the analytical methods depend are shortly stated in each article, and under these headings are described the methods employed, and the precautions to be observed, the whole being arranged in separate paragraphs for facility of reference. This work promises to be very useful as a book of reference, and will enable the analyst to select without much labour the process most suitable to the work in which he is engaged. We recommend this book to the attention of analytical chemists, being convinced that it will be found to contain much valuable information in a very convenient form.

A Series of Chemical Problems for Use in Colleges and Schools, adapted for the Preparation of Students for the Government Science and Society of Arts' Examinations. By T. E. Thorpe, Ph.D., Professor of Chemistry in Anderson's University, Glasgow. With a Preface by Prof. Roscoe. Pp. 67. (London: Macmillan and Co.; Manchester: J. Galt and Co., 1870.)

THIS little book contains a number of useful tables and descriptions of the modes of calculation made use of in chemical science, illustrated by examples. Each section is followed by a series of questions, for the most part original, but some of which are selected from the examination papers of the Science and Art department and from the Owens College calendar. The subjects treated are Weights and Measures, Thermometric Scales, Correction of Volumes of Gases, Specific Gravity, Percentage Composition, Quantities of Reagents necessary to form certain Products, Combination and Decomposition of Gaseous Bodies, Determination of Atomic Weights, Calculation of Empirical Formulæ, and of the Results of Analysis, Specific Heat, Latent Heat, and Calorific Power. The collection of questions will doubtless be useful to students preparing for examination, and to teachers endeavouring to familiarise their pupils with the details of chemical investigation.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Professor Max Müller and the Insulation of St. Michael's Mount, Cornwall

THOUGH very much gratified at the fact that something from my pen has prompted Prof. Max Müller to give us another "Chip from his German Workshop," I was by no means prepared for the mode of treating materials which he has adopted in the Chip to which I refer—his paper on the "Insulation of St. Michael's Mount."*

As the author states, I read a paper to the British Association in 1865, at Birmingham (not Manchester as he supposes), and in April 1867, delivered a Friday evening lecture at the Royal Institution; each having the same title as his paper just mentioned.

With the exception of fifteen lines in the Report of the Association, the first was never printed either *in extenso* or in abstract. I conclude from the Professor's paper, however, that he saw a notice or report of it in some newspaper or journal; but, if so, I can only say that it was neither written nor corrected by me, nor with my knowledge, and that I decline to be responsible for it.

The lecture in 1867 was delivered from very brief notes, but an abstract of it was subsequently written by myself for the "Proceedings of the Royal Institution," and, printer's errors excepted, contained my opinions on the question.

It is clear from Prof. Max Müller's paper that a copy of this abstract was in his possession when he wrote his article. Indeed, the "short account" of the Mount which he "quotes" from me is from it, and not from the paper of 1865. Though substantially correct, this quotation contains three errors which may as well be set right in passing. On page 330 "very high water" and "very low water" (lines 9 and 10) should be "every high water" and "every low water," and "the total isthmus" (line 13) should be the "tidal isthmus."

In the paper of 1865 the following points were assumed:—(1) that the old Cornish name of the Mount was "Cara clowse in Cowse;" (2) that it had been correctly translated as the "hoar rock in the wood;" (3) that the name was appropriate when given; and (4, on the authority of Dr. Boase and Dr. T. F. Barham) that Florence of Worcester expressly stated that "the Mount was formerly five or six miles from the sea, and enclosed with a very thick wood." Though fully aware that each of these points might be open to question, I supposed them to have, at least, a fair amount of evidence in their favour, and hence concluded that the insulation of the Mount had taken place sincet he introduction of the old Cornish language into the district. Now, such insulation must have been the result of the encroachment of the sea merely, or of a more or less general subsidence; and my object was to show that it was the latter. In order to do this I attempted to dispose of the first hypothesis—insulation by encroachment without subsidence. A careful personal investigation of the Mount and the mainland, and the evidence of an old intelligent native, led me to the conclusion that to take the average retrocession of the cliff at ten feet in a century would probably be an excessively high estimate, and that, even at this rate of waste, "the hypothesis of insulation by encroachment only, appeared to demand the belief that at least twenty thousand years ago Cornwall was inhabited by men who spoke a language which prevailed in the same district to within a very few centuries of our own time, and which, from its similarity to the Welsh, might be said to be spoken still by a large population within our own island." Believing this conclusion respecting the antiquity of the Cornish language to be utterly untenable, I at once rejected it, and, with it, the hypothesis of insulation by encroachment merely, remarking of it that it "squandered time most lavishly."

I am, of course, delighted to find myself supported by Prof. Max Müller in the rejection of this vast antiquity of the Cornish language, for he tells us (p. 364) that it "would completely revolutionise our received views as to the early history of language." It is strange, however, and probably only to be accounted for by his trusting to a newspaper report of my paper, that he supposes that, instead of rejecting it, I have "adduced evidence in support" of this great antiquity (p. 354). The point of my argument was that the hypothesis of "insulation by encroachment without subsidence" could not be admitted, *because it led to an untenable philological conclusion.*

Turning next to the hypothesis of insulation through subsidence—the only alternative consistent with the assumptions made at the beginning—I proceeded to show that the numerous submerged forests which skirted the western coasts of England, and of which a good example in the Mount's Bay had been described by Dr. Bouse in 1822,† were to the geologist sufficient and satisfactory proof of a general subsidence of the country; and then pointed out that whilst, on the one hand, this change of level could not have occurred within the last 1,900 years, since, about 9 B.C.,

* "Chips from a German Workshop," vol. iii. pp. 336—357 (1870).
† Trans. Roy. Geol. Soc. of Cornwall, vol. ii. p. 129 *et seq.*

the Mount was described by Diodorus Siculus in terms which apply admirably to it at present; on the other hand, it could not have taken place in times geologically remote, since the forests consisted of plants still indigenous to the district, and contained remains of beetles retaining all their beautiful colours, as well as the horns of the red deer, which man had fashioned into tools; that, in short, there was nothing compelling the belief that the subsidence happened very much before the time of Diodorus.

The paper concluded thus:—"A careful consideration of all the facts of the case, as well as of the related phenomena, points decidedly to the conclusion that, since Cornwall was inhabited by a race speaking the old British language, St. Michael's Mount was a hoar rock in a wood, and that its insulation resulted from a general subsidence of the country."

From the foregoing sketch it is obvious that, at that time, I supposed the subsidence to have taken place not much more than 2,000 years ago, and this was well understood by Sir C. Lyell and others, who took part in the discussion on the paper. Indeed, the eminent geologist just named, to whom I soon after sent the manuscript, after speaking of the attention I had given to the question (Principles, vol. i. p. 543, 1867), adds, "It is a somewhat forced hypothesis to assume that, whereas a retrospect of nineteen centuries displays to us the Mount geographically the same as it is now, yet shortly before that time, when Cornish was spoken, there was a sinking down and submergence of a wooded tract;" thus stating his dissent from the view which, as he knew, I then held.

After reading the paper of 1865, I devoted considerable attention to the literature of the subject, and in the lecture of 186 stated that the tradition of the Mount having been five or six mile from the sea, and enclosed in a very thick wood, was first mentioned, not by *Florence* of Worcester, who died in 1118, and who nowhere alluded to the Mount, but by *William* of Worcester, who visited Cornwall about 1478, or 360 years further from th period to which the tradition was supposed to point, thus rendering the tradition itself of very much less value; that the alleged old Cornish name assumed so many forms, and there was so much uncertainty about its exact import, as to render it improbable that it had any value as evidence; and that the submerged forest in Mount's Bay was known much earlier than I had supposed, having been mentioned by Leland, 1533-40.

The object of the lecture was to show that there had been a general subsidence of the country, that this was prior to the time of Diodorus, and that the era of the cavern deposits in South Devon was much earlier still. In fact, the insulation of the Mount, which was held to synchronise with this subsidence, was used as the first, or most modern, of a series of stepping stones leading backwards towards the era of the ancient Cave-men of Devon.

The printed abstract of the lecture closes with a recapitulation, which contains the following passage:—"Nineteen centuries ago it (the Mount) possessed a safe harbour, so that its insulation must have been effected long before; it was at one time unquestionably a hoar rock in a wood, but in all probability it had ceased to be so long before any language now known to scholars was spoken in the district. Prior to its insulation was the era of the growth of the forests now *submerged* along our entire seaboard," &c.

I am not quite sure to what Prof. Max Müller refers when, speaking of this lecture, he says, "Mr. Pengelly has somewhat modified his opinion" (p. 333). If to the opinion that the insulation of the Mount was due to subsidence, he is unquestionably in error, as I have never wavered on this point. If to that of the old British language having been spoken in Cornwall 20,000 years ago, my reply has already been given—"I never held it." But if it be to the opinion that there was a fair amount of evidence in favour of the traditions of the enclosure of the Mount in a thick wood, and of its alleged old British name; instead of modifying, I had discarded it in 1867, and with it, as a matter of course, the necessity of believing, on the one hand, that the Cornish language must have had an antiquity of 20,000 years; or, on the other, that the subsidence took place but little more than 2,000 years ago. It is unnecessary to say how very much I am gratified at finding the traditions discarded also by Prof. Max Müller (see p. 355 *et seq.*)

Before concluding, I may state that in July 1867, I read a paper to the Devonshire Association, under the title of "The Antiquity of Man in the South-west of England," which was simply an amplification of the lecture of the previous April, and was printed *in extenso* in the following October.* It contained a few points of interest which had come to my knowledge after the Royal Institution lecture was delivered; such as the fact that the earliest mention of a British name was made, not by Carew in 1602, but by Norden in 1584 and Camden in 1586, who concurred in giving it as "Careg Cowse," which the first rendered the *Grey rock*, and the second *Rupis cana*; the fact that the name occurred in two different forms in Carew; and the fact that there was some error in William of Worcester's statement about Pope Gregory's grant to the Church on the Mount in the year 1070, there being no Pope Gregory at that time.

It is not my intention at present to enter on a consideration of the question, "Have geologists," as Professor Max Müller supposes, "left it doubtful whether the insulation of the Mount was due to the washing of the sea-shore, or to a general subsidence of the country?" or, "May not the Mount have always been that kind of half-island which it certainly was 2,000 years ago?" My object is simply that of correcting an error into which the Professor has fallen respecting my opinion, apparently in consequence of using an anonymous and probably incorrect report of a paper read in 1865, instead of an authorised abstract of a lecture delivered in 1867,—an error, however, which can scarcely be regretted, since to it we owe a "Chip" of great interest and value.

W. PENGELLY

Glycerine Solutions of Pepsin and other Substances

IN NATURE of December 29, Prof. M. Foster calls attention to the method of making glycerine extract of pepsin pursued by Von Wittich, and remarks with reason that the means hitherto adopted for preparing pepsin for medical purposes are clumsy and inefficient. There is, however, one exception, a mode of preparation which has long been in use, and which is by no means inefficient. This will be found to possess some practical advantages over the process of extracting the fresh mucous membrane with glycerine, while from it the glycerine solution can be prepared quite as pure and clear, and as strong as by maceration.

As long ago as 1858 (Archives of Medicine, vol. i. pp. 269-316) I described a method of obtaining the active digestive material from the pig's stomach, which answers perfectly, and has been employed in practice ever since. It simply consists in quickly drying the mucus expressed from the stomach glands upon glass plates.* The dried mucus is then powdered and kept in stoppered bottles. It retains its properties for years. Eight-tenths of a grain will dissolve *one hundred grains* of coagulated white of egg.

Now, from this powder is easily prepared by solution in distilled water a perfectly clear and colourless digestive fluid of great activity, which *can be readily filtered*.

Some years ago I found great advantage from subjecting tissues to the action of a very small quantity of this solution in glycerine, and keeping the whole at the temperature of 100° for some hours. By this process the elements of the tissue were softened, and could be dissected from one another readily for examination under the highest magnifying powers.

No doubt there is much to be learnt concerning the nature of the action of such substances upon tissues by the use of glycerine solutions. For microscopical work glycerine is of more use than any other medium. Not only may various substances be removed from tissues, but others may be introduced, and the tissue subjected to the action of various reagents without destroying it. In fact, the action may be regulated with the greatest nicety. Nearly all the tests required in microscopical examination may be dissolved in glycerine ("How to Work with the Microscope," p. 297, 1867) and tissues of the most delicate character may be preserved in it, and will retain their microscopic characters for years, *if care be taken to obtain the best and strongest glycerine.*

LIONEL S. BEALE

Tails of Comets, Solar Corona, and Aurora

UNDER this heading, in your issue of 5th inst., you report a paper by Prof. Osborne Reynolds, M.A., read at a meeting of the Manchester Literary and Philosophical Society, Nov. 29 last. This paper sets forth that the tails of comets, the solar corona, the aurora, and the Zodiacal lights are due to the ether which "fills" space. Comets' tails, as stated by the Professor, in his paper, are an effect due to the medium through which it

* This Pepsin is prepared for medical purposes by Messrs. Bullock and Reynolds, 3, Hanover Street, Hanover Square.

passes being heated and illuminated by the comet; and that the other phenomena are also due to the ether.

I rely that you will do me the justice to allow space for me to remind your readers that the theories which Prof. Reynolds so emphatically calls *his*, were propounded and published by me sixteen years ago, and noticed by most of the press throughout the world.

The following quotation from my pamphlet (now out of print) will enable your readers to judge of the correctness of these statements :—

"It was noticed, in reference to 'Biela's comets,' that the smaller one, which I call the *tertiary* comet, and which travelled in a separate or distinct orbit, that a kind of *rein*, or stream of light, joined the two heads, the stream of light being *larger* as it approached the head of the *larger comet*. This stream of light, I think, proves most satisfactorily that the 'tails' of comets are nothing more than the illuminated or heated *medium* through which the comets pass. The *cylindrical* appearance which these 'tails' sometimes present, I believe is occasioned by the *rotary motion* of the comets (or infant worlds) on their respective axes. *The increased number of 'tails'* to a comet is occasioned by the interposition of one or more secondary or tertiary comets, intercepting the 'tail' of the superior body, the direction of which 'tails' would be determined by the position of the said intercepting bodies, aod the variety of *appearance* in connection with the point from which they were viewed," &c.

Bayswater, Jan. 9 J. BEDFORD, Ph.D.

The Artificial Introduction of Plants

THE remarks on page 142 of your number of December 22, on the proposal of the Manchester Field Club to introduce plants foreign to the district, ought to be printed in red letters. The geographical distribution of plants is not the least interesting branch of botanical study, and is, besides, important in its bearings upon other natural sciences, such as geology and meteorology, and as such has formed the subject of laborious and intelligent research among various eminent naturalists.

Amateur botanists can carry on their favourite pursuit in two widely-different ways: they can play at science, and so amuse themselves to their own satisfaction, may be, but with little advantage to what they propose to admire, or they may patiently and conscientiously work and observe within their own sphere of research, and thus be able to render, as occasion serves, very real service to science at large, more, perhaps, than they are aware of at the time, and certainly to earn very genuine pleasure for themselves.

Not that I mean to insinuate that the Manchester Club are playing at science, but I warmly agree with your remarks that a mistake is being made by them in this respect. The instance is not a solitary one, even in my limited experience. Not long ago I found myself protesting against the notion of an amateur botanist (in England), who was endeavouring to introduce a species into a new locality. This is about as detrimental a proceeding in its way as that of the wanton eradication of a species from a neighbourhood.

I write *con amore*, for I happen to live and botanise in a part of Europe lying off the line of railways, therefore little visited, but possessing an interesting and somewhat peculiar flora, and am not unfrequently applied to by eminent botanists for information as to the real existence in the district of plants alleged with more or less of truth to be indigenous here.

Science Teaching

IN an article in NATURE, December 29, 1870, on "Science at School Boards," the teaching capabilities of this country appear to me to be under-rated; I refer especially to the following passage:—"We would advise that some attempt be made to teach some quantum of Natural Science somehow. The present masters will probably be utterly ignorant of any branch of Science!"

If such is the fact, I would ask what have the training-schools been doing for years past? Most of these schools have university men as teachers, or men who have obtained a lectureship; and surely they have turned out students of two years' residence, capable of teaching one or more of the elementary branches named by the writer of the article referred to.

Does Dr. Lankester really think that the majority of the trained certificated masters of this country are incompetent to teach elementary physical geography? Many of these masters possess, I believe, a certificate for teaching Science, in virtue of having passed an examination under the Science and Art Department; and surely the examiners employed by the Department are such men as even Dr. Lankester would not ignore.

I feel confident that so far as teachers are concerned the matter is not so bad as Dr. Lankester imagines. The Revised Code checked all science teaching in elementary schools, but only let the Committee of Council accede to the appeal now made, and they will find plenty of masters able and desirous of teaching the elements of Science in our elementary schools.

There are two obstacles to be overcome before good results can be obtained. There must be better and ampler teaching power employed in our schools, so as to give the master the opportunity to carry out consecutive teaching; and then people generally must be made aware of the importance of Science to the artizan class, parents must be taught to appreciate the efforts made for their children. I will venture to say that more than half the work of the best teachers of this country is neutralised by the indifference or ignorance of parents.

Wisbech, Jan 3 SAMUEL H. MILLER

The Frost

I REMARK in the "Notes" of your last number, it is stated that "the lowest temperature at Blackheath was 15·3° F., on the night of the 24th December."

Now, assuming the correctness of the instrument from which this observation was taken, the locality must be much more protected from frost than that in which I reside. I have two good registering thermometers placed in a N.E. aspect, at about twenty-five or thirty feet from the ground—the one an upright mercury (Beck, Cornhill), the other a horizontal spirit tube (Hughes, Fenchurch Street), and the readings, which correspond exactly, were as follows:—

On the night of 23-24 Dec. 12° F., and at 7 A.M. on the 24th 14°. The maximum temperature (about noon) on the 24th was 24°, and at 11 P.M. the mercury had dropped to 16°.

On the night of the 24-25th the minimum was 9° F., at which point the register stood as late as 7 A.M. on the 25th, and even at 10 A.M. it had only risen 1° (10° F.)

I send you these observations, which I believe to be very correct, as they may be of some interest to meteorologists in our neighbourhood.

Blackheath, Jan. 9 JOHN CAREY

[It will be seen that these figures correspond very nearly with those given in our "Notes" this week.—ED.]

ON Sunday morning, 1st inst., a standard terrestrial radiation thermometer (exposed here on the previous evening) registered the unusual low temperature of 6·3 °F. or 25·7° below the freezing point.

The instrument was placed a few inches above snow covered grass on a gravelly soil, and exposed to nearly the whole sky.

Sharks announcing their own Capture

LIEUT. C. H. TAYLOR, of H.M.S. *Cossack*, in his Remark-book for 1869-70, alludes to the following ingenious mode of making sharks announce their own capture. It appears that the island of Johanna, at the north end of the Mozambique Channel, is frequently visited by numerous sharks, whose flesh is esteemed as an article of food by the natives, who also prize the skin and oil for domestic or commercial purposes.

The Johanna men, however, being too lazy to fish in what might be termed a legitimate manner, have recourse to floating traps, with line, hook, and bait, and supporting above water a pole and basket. A bight of the line near the raft is attached to a bolt or toggle, which, when in place, keeps the pole in an upright position, but the moment a strain is brought on the line by the fish being hooked, the toggle is withdrawn, causing the pole and basket to fall, which is a signal to the people on shore that the prey awaits their coming. Extraordinary Meteor

THE following account of an extraordinary meteor occurs in a letter I received from a brother who is a missionary stationed in Agra. He does not give the exact place where he was at the time, but it must have been very near to Agra. The letter is dated Agra, 24th November, 1870. A missionary from Allahabad was with him when he saw it. ROBERT GRYSON

Mills Hill, Chadderston, near Manchester

"Agra, Nov. 24, 1870

"I recently saw a marvellous meteor. I was in camp, and had risen for an early march a few minutes before 3 A.M. on Nov. 4th. I was standing under the shade of a cluster of trees, when a sudden flash of light fell around. Two or three camp fires were blazing near, and at first I thought it might be a sudden flare up from one of them, but on casting my eyes up towards the heavens, I saw a large oval light, stationary. It appeared to be composed of a large number of irregularly-shaped, differently-sized stars, yet so closely packed as to form one light, yet giving the whole a sort of dappled appearance. At first I was struck dumb with amazement—thought it must be some mental illusion, or that my eyes were playing me false. But as I gazed it remained steadily fixed. ——— of Allahabad was with me. I roused him. He was soundly asleep, and some seconds passed in waking him up. In the interval it appeared to have been lengthened, nearly, though not quite, by a straight line, and as we gazed it assumed the shape of a large magnet, with the upper limb rather shorter than the other. It then gradually expanded, diminishing in brightness as it increased in size, assuming a wavy, serpentine form, though keeping much to a horse-shoe shape, until it became so attenuated as to be no longer visible. It must have continued in sight five minutes. It was seen by all the servants, and one of them cried out '*Bhagwanka sela hae*,'* by which he appeared to mean that in his opinion the Almighty was amusing Himself with fireworks; literally, 'It is God's sport or amusement.'"

* I cannot be quite sure of these words, not knowing the original language in which they were spoken.—R. G.

NATURAL SCIENCE AT CAMBRIDGE

THe following is a list of the Scholarships and Exhibitions for proficiency in Natural Science which are likely to be offered in Cambridge during the present year:—

TRINITY COLLEGE.—One or two of the value of about 80*l.* per annum. The Examination will be in Easter week, and will be open to all undergraduates of Cambridge and Oxford. Should one Scholarship only be assigned, preference will be given to the candidate who shows the greatest proficiency in Physiology and the allied subjects. Further information may be obtained from the Rev. E. Blore, Tutor of Trinity College.

ST. JOHN'S COLLEGE.—One of the value of 50*l.* per annum. The Examination (in Chemistry, Physics, and Physiology, with Geology, Anatomy, and Botany) will be on the 21st and 22nd of April, and will be open to all persons who are not entered at the University, as well to all who have entered and have not completed one term of residence. In this College, moreover, Natural Science is now made one of the subjects of the regular College examination of its students at the end of the academical year (in May); and Exhibitions and Foundation Scholarships will in consequence be awarded to students who show an amount of knowledge equivalent to that which in Classics or Mathematics usually gains an Exhibition or Scholarship in the College. In short, Natural Science is on the same footing as Classics and Mathematics, both as regards teaching and rewards. Further information may be obtained from the Rev. T. G. Bonney, Tutor.

CHRIST'S COLLEGE.—One or more, in value from 30*l.* to 70*l.*, according to the number and merits of the candidates, tenable for three and a half years, and for three years longer by those who reside during that period at the College. The examination will be on March 28, and wil be open to the undergraduates of this College, to non-collegiate undergraduates of Cambridge, to all undergraduates of Oxford, and to any students who are not members of either university. The candidates may select their own subjects for examination. Besides these there are three other Exhibitions perfectly open, which are distributed annually among the most deserving students of the College.

CAIUS COLLEGE.—One of the value of 60*l.* per annum. The examination will be on March 30, in Chemistry and Experimental Physics, or Zoology, with Comparative Anatomy and Physiology, or Botany, including Vegetable Anatomy and Physiology.—Scholarships of the value of 20*l.* each, or more if the candidates are unusually good, are offered, for Anatomy and Physiology, to members of the College.—Gentlemen elected to the Tancred Medical Studentships are required to enter at this College; these studentships are four in number, and the annual value of each is 113*l.* Information respecting them may be obtained from B. J. L. Frere, Esq., 28, Lincoln's Inn Fields, London; and respecting the other scholarships, from the Rev. N. M. Ferrers, Tutor of the College.

CLARE COLLEGE.—One or more of the value of 50*l.* per annum. The examination (in Chemistry, Chemical Physics, Comparative Anatomy, and Physiology, and Geology) will be on March 23, and will be open to students intending to begin residence in October.

DOWNING COLLEGE.—One or more, according to the merits of the candidates, of the value of 40*l.* per annum. The examination (in Chemistry, Comparative Anatomy, and Physiology) will be in March, and will be open to all students not members of the University, as well as to all undergraduates in their first term.

SIDNEY-SUSSEX COLLEGE.—Two of the value of 40*l.* per annum. The examination (in Heat, Electricity, Chemistry, Geology, Physiology, Botany) will be in October, and will be open to all students who may enter on the College boards before October 1.

Although several subjects for examination are in each instance given, this is rather to afford the option of one or more to the candidates than to induce them to present a superficial knowledge of several. Indeed, it is expressly stated by some of the colleges that good clear knowledge of one or two subjects will be more esteemed than a general knowledge of several.

Candidates, especially those who are not members of the University, will, in most instances, be required to show a fair knowledge of Classics and Mathematics, such, for example, as would enable them to pass the Previous Examination.

There is no restriction on the ground of religious denomination in the case of these or of any of the Scholarships or Exhibitions in the Colleges or in the University.

Further necessary information may be obtained from the Tutors of the respective Colleges.

It may be added that Trinity College will give a Fellowship for Natural Science once, at least, in three years; and that most of the colleges are understood to be willing to award Fellowships for merit in Natural Science equivalent to that for which they are in the habit of giving them for Classics and Mathematics.

EXPLORATION OF THE PERENE (AMAZONS) RIVER

ON the 28th November the Peruvian Government published the report of the expedition sent to examine the capabilities of the Perene river and neighbouring country, and the slope of their territory towards the Atlantic. This river, which is a branch from the Vcuyali, rises near Tarma, the capital of the Department of Junin, and flows through the country of the Chunchamayo Indians, a wild tribe, hostile to the Peruvians and but little known to them. The soundings were found to give from three to five fathoms in depth and the width was about 100 yards. The course of the river was east for 1,000 yards from its confluence and then north.

In the valley of Chunchamayo the forests consist of trees of extraordinary size, and the villages are numerous. According to Padres Amich and Sobrevista, the Indians belong to the tribe of the Amayos. The chief object of search of the expedition was the Cerro del Sal, or the Salt Hill, from which the Indians obtain that necessary article. The expedition consider they ascertained the region of it in a sandstone formation.

The expedition observed plantations of cocoa (coca?) and Indian corn, and on the banks of the river fishing huts, with nets and fittings for catching and salting fish. What was most striking was an iron furnace of a square form, about two yards high, and five feet each way, constructed of bricks eighteen inches long. It was worked with a double bellows, and supplied with coal, wood, and pounded ore. Water for the tanks was brought from a height in landers of bark hides. There were about twenty or thirty hundredweight of cast-iron. The whole excited the admiration of Mr. James Greg, owner of the Lima Iron Foundry, who accompanied the expedition.

The party fully ascertained the presence of salt, and considered they had found the vein of salt reputed to be ten miles in length, as they found it consisted of earth with particles of salt and quartz crystals. On digging down they found that the salt increased.

The Indians use the bow and arrow, and seemed much afraid of firearms. The commander recommends as the best mode of subduing them that the Salt Hill shall be taken possession of. It is considered that a navigable point has been found about 200 miles from the capital City of Lima, and by means of which it can obtain communication with the Atlantic. The Government is strongly urged to send a more powerful expedition.

HYDE CLARKE

BRITISH DIATOMACEÆ *

IT is now some years ago since Mr. Van Voorst published for Messrs. Smith and Beck two volumes of a "Synopsis of British Diatomaceæ," by Prof. William Smith, of Cork, which were beautifully illustrated by Mr. Tuffen West. The latter volume of this Synopsis was published in 1856, and even then the number of new forms of these minute silicious Algæ had rendered necessary the preparation of a supplement which, however, owing to the death of the author, never appeared. Since 1856 many and important works and memoirs on the diatoms have been published, and not only have the pages of the Quarterly Journal of Microscopical Science contained numerous writings on this subject, but workers like Rabenhorst, Grunow, and Cleeve have continued to add to not only the number of species, but to the amount of our knowledge of the Diatomaceæ. We venture, nevertheless, to think that the time had not quite come to write anew a history of the British Diatomaceæ. The difficulty of finding good specific characters remains just as great as it was when Smith's work was published, and the number of local lists recorded has been too few to give us anything like an idea of the geographical distribution of these forms; still we should be sorry not to welcome one of Mr. Van Voorst's series of British Natural History works, a series of which we have every reason to be proud; almost their only drawback being incidental to the method in which the works of the series are published, viz. in numbers, by which it too often happens that there is a want of uniformity between the earlier and later portions of the work.

Dr. Donkin's work is to consist of two parts, "the first will be introductory, and contain a full account of the Diatomaceæ and a new classification based on their structure and mode of development;" and the second, which is to be published first, "will be synoptical, and give an accurate and succinct description of all the known British genera and species. The synonyms of each species will be fully given *with the view of rendering the work more valuable for the purpose of reference*." There strikes us as being something quaintly simple in the words we have italicised. Fancy an apology for giving synonyms, as if they were something or another that people did not care about!

Part one (pp. 1 to 14 and plates 1 to 4) now lies before us. The execution of the plates disappoints us. We know that the artist's right hand is very far from having lost its cunning, and yet the figures here are, to our mind, much inferior to the figures by the same hand in Smith's work. 500 diameters, too, is a large scale for the amplification, and will only unduly increase the number of plates—it does not appear either to have contributed to greater distinctness of detail. Plate 3 is open before us. Fig. 3 we should consider scarcely recognisable; and fig. 7 is greatly less true to nature in both outline and proportion than one also of the same species before us by Grunow.

The first family treated of in the text is the Naviculeæ. No synonyms are given to the genus *Navicula*, but we learn from the diagnosis and from the remarks in the text that *Pinnularia* Ehrb., as emended by Smith, is reduced to the rank of a synonym of this genus; so that Navicula will be a genus very full of species, and we venture to suggest that there will be great difficulty in many instances in determining whether to refer a species to the section with flattened or convex valves. The initials M. V. are used to express a view of the frustule, exhibiting the *median connecting zone*, and the *margins of the valves;* this we welcome as an improvement.

Perhaps this is hardly a fitting place to criticise very closely the species given in this part. Opinions may differ very widely indeed as to what is a species among these little Algæ, still we think it questionable if *N. didyma* var. Smith, Synop. vol. i. p. 53, quoted as a synonym to *N. smithii* De Breb. is not greatly nearer *N. smithii* var. *fusca* Ehrb. Again, we do not think that *N. hyperborea* Grun. is identical with *P. fusca* Ehrb.; it differs both in outline and details, and unless the difference in striæ is to be altogether given up, *Pinnularia forficula* O. M. cannot be regarded as synonym of *N. suborbicularis* Ehrb.; *N. nitescens* Ehrb., and *N. suborbicularis* Ehrb., are rightly kept as separate species, and we also approve of the separation of *N. subsalina* from *N. amphisbæna*. *N. latissima* Ehrb. is described as having striæ distinctly *granular*, how then can *Pinnularia divaricata* O.M., striæ distinctly *costate*, be regarded as a synonym? It will not do to separate some forms and bring others together exactly for the same reason. The habitats given are most meagre, and the work presents a contrast in this to the rest of Mr. Van Voorst's series. Even in cases where the author could have given Irish localities for rare and interesting forms, he has passed them over, and if we had not found a reference or two to the Lough Mourne Deposits in the County Down, we should have fancied that no Irish localities were to be given.

We have been thus candid in our notice because we believe it possible with care to remove from this work the signs of its being slightly premature. It only needs to keep to its promise and give the *synonyms* in full, and to give the *habitats* in full, at least for uncommon forms, and lastly, to make the figures more distinct, to make this "Natural History of British Diatomaceæ" a very valuable work.

W.

* "The Natural History of the British Diatomaceæ." By Arthur Scott Donkin, M.D. Part 1. Nov. 1, 1870. (London: J. Van Voorst, Illustrated with Plates by Tuffen West, F.L.S.)

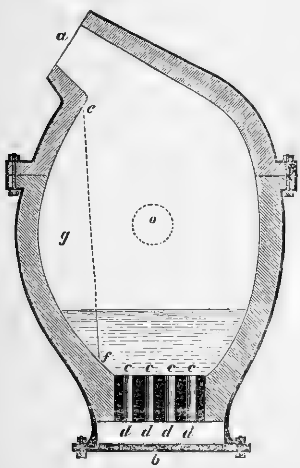
PAPERS ON IRON AND STEEL

No. II.—The Bessemer Process.

In this paper I propose to describe the general phenomena of the Bessemer process, and then to examine the chemical actions producing these phenomena and the changes they effect in the material operated upon.

In the first place the pig-iron is melted in a suitable furnace, usually in that form of furnace known as the "cupola." The melted iron is run from this by means of moveable troughs into the "converter," which is a pear-shaped spouted vessel, lined with fire-clay, "ganister," or other refractory substance.

This pear-shaped vessel, a vertical section of which in the upright position and without mechanical details is represented in the annexed figure, is truncated at the lower end, and thus a flat circular bottom is formed. This bottom, which is readily detached and renewable, is fitted with longitudinally perforated fire-clay cylinders shown in section at *cd*, *cd*, *cd*, *cd*, each perforation or clay tube being about one-half or three-quarters of an inch in diameter,



and all communicating with the space *d d*, into which opens the blast tube from a powerful blowing engine. The number of these blast holes varies from fifty or sixty to a hundred or more, according to the size of the converter.

The converter is mounted on trunnions so arranged that it may turn on a transverse axis crossing about the middle of the vessel, as shown by the dotted circle *o*. The turning is effected by hydraulic machinery, controlled by levers readily worked by a man who stands on a platform in full view of the converter. In order to receive the charge of melted iron, the converter (the lining of which has been previously raised to a bright red heat) is turned over so that the dotted line *e f* becomes horizontal, and corresponds to the surface of a full charge. The belly *g* of the converter is so curved that it shall in this position retain the whole charge without any of it reaching the blast holes at *f*, or the mouth at *e*, and yet allow the whole charge to be readily "teemed" by turning the converter a little further down.

When the full charge is thus received in the belly of the converter, the blast is turned on, *after which* the converter is turned to the upright position, as shown in the figure, and the melted metal then stands directly over the perforated bottom. As will thus be seen, all the fluid metal above the openings is now resting upon a bed of air, and is only prevented from falling through by the blast being maintained at a pressure exceeding the falling force of the column of liquid above it. It would fall through these orifices into the blast-way and do serious mischief should the blast be stopped or slackened for an instant, or should the converter be turned upright or overcharged before the commencement of the blast. An accident of this kind but rarely happens, though it is by no means an unknown casualty.

The "blow," as it is termed, now commences; the hundred streams of air tear through the pool of melted iron, and a huge flame roars furiously from the mouth of the converter. At irregular intervals magnificent cascades of brilliant coruscating sparks are belched forth, and the dazzling spray as it dashes against the walls of the flame-shaft rebounds with redoubled splendour, each glowing globule being shattered by the shock and bursting into rescintillating fragments. The loud-bellowing blast roars on monotonously, but the flame becomes brighter and brighter continuously, and grows in length and breadth as it increases in brilliancy, until at the end of about ten minutes it attains its maximum, when its splendour is painful to the eye, and yet so fascinating that few who see it for the first time can turn their dazzled eyes away. The spark eruptions still burst upwards from time to time, and still dash against the brickwork and the ground, and still reverberate in fiery splinters, but their appearance has changed. They are now no longer red hot, or yellow hot, or white hot, but have a curious purple luminosity different from anything one has ever seen before. If it is daytime and the sun shining, the sunlight out of doors has a sickened partial-eclipse aspect when viewed directly after gazing at the flame, and at night the ordinary gas lights appear red and smoky.

After five or ten minutes' continuance of this maximum splendour, the flame is seen to contract somewhat, and presently the ponderous vessel turns a very deliberate summersault, the flame disappears, but the uninitiated spectator is startled by a new display; for as the converter rolls smoothly over, it disgorges a continuous stream of sparks which its rotation spreads out in a fan-shaped volley, extending from end to end of the building, and reaching the roof, descends in a broad sheet of fiery hail. This is the transformation scene which concludes the first part of the performance; for now the dazzle of the flame and the roar of the blast ceases, and a general lull intervenes.

The trough from the cupola is now swung round to the mouth of the converter, a red glow is seen to creep along it, and starry sparks dance above as it advances. This is the spiegeleisen coming from its cupola by the same path as conducted the main charge. The spectator should now change his position, and if possible find a standing place from which he may look into the mouth of the converter. At first he will distinguish nothing but a yellow glare, but by steadily fixing his gaze, he will presently, and rather suddenly, distinguish the surface and limits of the pool of melted metal. He will see that as the spiegeleisen pours into it, a furious ebullition takes place. At the same time a great mass of pale blue flame issues from the mouth of the converter, but with a quiet, leisurely waving that contrasts curiously with the previous roaring jet of white flame. This flame has but very little intrinsic luminosity, yet at night it lights up all the surrounding objects with a singular brilliancy, a sort of exaggerated theatrical moonlight effect, which is the most remarkable to a spectator outside, who on a misty night sees the long streams of ghostly light pouring through every opening of the building in pallid beams, that under favourable conditions may be traced for above a quarter of a mile. I have seen them projected in bright discs upon the face of low clouds, and visible through the whole of their intermediate course.

When the flow of spiegeleisen has ceased, the trough is moved aside and a large counterpoised arm bearing the "ladle" is swung round upon an hydraulic piston, which forms at the same time its axis and lifter. The ladle, a large lined iron pot, is adjusted under the mouth of the converter, which is now tilted a little more, till the melted metal is poured out in a thick brilliant white-hot stream accompanied from time to time with great slabs of cinder of a darker colour which float upon its surface as it pours, and form a thick scum covering the contents of the ladle. When all the fluid metal is poured into the ladle, the converter is tilted over till completely inverted, and the remaining viscous mass of cinder drops out in a glowing heap upon the floor.

During these proceedings a set of workmen have been preparing the moulds in which the ingots of steel are to be cast. These moulds are of cast-iron, nearly cylindrical, being larger at bottom than top, and open at both ends. They have lugs or handles at top by which they are lifted. They stand upon a tile, and are well packed round the bottom with sand to prevent the outflow of the melted steel. While the blow was proceeding these were arranged in an arc of a circle whose radius exactly corresponds with the length of the arm bearing the ladle.

The ladle is now swung round and adjusted till it stands directly over the first of this row of iron vases, and a plug is released by which a hole in the bottom of the ladle is opened. Through this the steel is poured into the ingot. When the first is filled the plug is closed, the ladle swung round to the second mould, and so on, till all the steel is thus cast into ingots, the size of which varies with the kind of work for which the steel is required. A thin steel plate is placed on the top of each casting immediately the mould is filled, and over this a bed of sand is placed, and speedily and firmly pressed down.

As soon as the ingots have solidified, and while they are still glowing, the moulds are lifted off them by means of an hydraulic crane, and afterwards the ingots are picked up by tongs attached to the same machinery, and are carted away, all red hot, to the hammer-shops, where they are thumped and rolled or otherwise tortured into their required forms of rails, tyres, plates, &c.

The above are the leading phenomena of the Bessemer process; the chemical actions producing them, and the changes wrought in the pig-iron and spiegeleisen, will be treated in another part of this paper.

W. MATTIEU WILLIAMS

NOTES

OWING to Mr. Lockyer having been summoned to Malta to give evidence at the court-martial on the commander of the unfortunate *Psyche* (which we regret to hear has not been saved), we are unable to give a detailed report of the proceedings of the Sicilian Eclipse Expedition. We understand that Mr. Brothers, who was stationed at Syracuse, obtained five photographs of the Eclipse during totality. One of these shows the corona "as it was never seen on glass before." At Augusta very little was seen; but at Syracuse, the southernmost station of all, the clouds which concealed the earlier stages of the Eclipse, passed away from the sun about five minutes before totality, "disclosing," writes Mr. Brothers, "a scene I shall never forget." Next week we shall hope to be able to give a complete account of the results of the Expedition, and their bearings on any increase of our knowledge of Solar Physics.

PROFESSOR CARL GUSTAV BISCHOF, who died at Bonn on the 29th of November last, was equally distinguished as a chemist and a geologist. He was born in 1792, near Nüremberg, in Bavaria, and was consequently at the time of his death in his seventy-ninth year. In 1810 he entered the University of Erlangen, where the lectures of Prof. Hildebrandt induced him to devote his study to chemistry and physics. In 1816 he succeeded to his master's position, and brought to a conclusion his "Lehrbuch der Chemie." In 1822 he removed to Bonn, in which University he occupied the position of Professor of Chemistry from that time till his death. Shortly afterwards, however, he began to pay more attention to subjects connected with chemical and physical geology, publishing a large number of treatises of sterling merit, an enumeration of which is given in the *Geological Magazine* for January. In 1841 his "Physical, Chemical, and Geological Researches on the Internal Heat of the Globe," were published in London, and in 1854 an enlarged translation of his "Lehrbuch der chemischen und physikalischen Geologie," was issued by the Cavendish Society. He was a Foreign Member of the Geological Society of London, and had received from that body the gold Wollaston medal.

THE following courses on Anatomy and Physiology at Cambridge are announced for this term:—Zoology and Comparative Anatomy, three days a week, by Prof. Newton; Anatomy and Physiology, three days a week, by Prof. Humphry; Practical Anatomy, three days a week, by Prof. Humphry and Mr. Carver; Practical Histology, by Mr. Martin, under the superintendence of Prof. Humphry, once a week, with a Microscopical Demonstration once a fortnight; Physiology, three days a week, by Dr. Michael Foster, with Practical Instruction in the Physiological Laboratory daily.

PROFESSOR P. M. DUNCAN will shortly commence a course of Lectures at King's College, London, which is open to the public, and to those who are going in for examinations. It will comprise ten lectures on the Principles of Biology in its relation to the Succession of Life on the Globe, five on Astronomical Geology, and the rest on the Principles of Geology. The course will open on Saturday, Jan. 28, at 11.30 A.M., and will be continued through the Lent, Easter, and Michaelmas terms.

DR. E. SYMES THOMPSON will deliver two lectures at the Gresham College, Basinghall Street, "On the Circulation of the Blood," on Saturday the 14th and Monday the 16th of January, at seven o'clock, which will be free to the public. It is proposed next term to continue the course "On the Organs of Respiration and Circulation in Health and Disease."

IN answer to several inquiries, we may state that the penny lectures delivered at the Hulme Town Hall by Prof. Huxley and others, to which we referred last week, are published by Messrs. Heywood, of Manchester.

WE stated in our last number the lowest temperature recorded at Blackheath during the recent frost to have been 15·3° F. on the night of December 24. More recent tables published in the *Gardener's Chronicle* give the minimum as 9·8° on the 25th. From December 22nd to January 4th the temperature at Blackheath ranged between 6·9° below the mean of fifty years, on January 4th to 18·7° below the average on December 25th. The minimum above mentioned occurred at 7 A.M. on Christmas Day, being lower than any temperature since the morning of Christmas Day 1860, when it was 8°. In the midland and eastern counties, where the cold was most severe, it is feared that much injury has been done to vegetation, especially to the evergreens. In Paris the frost has been equally intense. In a paper recently read before the French Academy of Sciences, it was stated that during December the temperature only rose above the freezing point on nine days. In the fifty years from 1816 to 1866 the average temperature for the month of December has been 3·54° above zero C. or about 38° F. The average temperature of this last December has been 1·07° below zero C. or a little above 30° F.

Engineering for Jan. 6 gives a ground plan and elevation of the proposed building for the united accommodation of the Society of Arts, Statistical Society, Royal Colonial Institute, Iron and Steel Institute, Institute of Actuaries, Ethnological Society, Anthropological Society, Photographic Society, Social Science and Law Amendment Society, Juridical Society, Victoria Institute, Royal Archæological Society, Meteorological Society, East India Association, and others which will not find a home in Burlington House. The proposal is to adapt for the purposes of these Societies the block of buildings, No. 4, Westminster Chambers, Victoria Street, together with a triangular piece of vacant ground, about a fifth of an acre, now lying waste in the rear of the Westminster Chambers. With these resources it is calculated that ample room will be obtained for the needful offices, reading-rooms, &c., as well as for libraries and museums, and a large lecture theatre capable of holding 1,200 persons.

THE Meteorological Office is now issuing daily Wind Charts of the British Isles, which are published in the *Mercantile and Shipping Gazette*. The chart indicates the direction and force of the wind at a number of different stations on the coast of Great Britain and Ireland, and will be found of great value to all interested both in shipping and in meteorology.

WE have received a copy of the Inaugural Lecture delivered by Prof. M'Coy at the opening of the Industrial and Technical Museum of Victoria, at Melbourne, to which is appended a short sketch of the contents of the Museum. The most important collections are illustrations of the manufacture of glass and of pottery, a series of 1,300 specimens of Victorian rocks and minerals, and 500 specimens of New Zealand rocks; a phytological collection to illustrate the natural productions of the Australian colonies, and a series of Australian ores, slates, building-stones, &c. Courses of lectures on technical subjects are delivered at the Museum.

THE first number has been issued of a *Journal of the London Institution*, containing short reports of lectures which have been delivered and a programme of proceedings in the future. In future numbers it is proposed to devote considerable space to Notices of New Books presented to the General Library, to Bibliographic and Scientific Notes and Queries, and to Records of Laboratory Work.

WE have received the first number of *The Quarterly Journal of the Amateur Mechanical Society*, the object of which is stated by the honorary editor, the Rev. J. Lukin, to serve as a medium of mutual information upon all points connected with mechanical manipulation. The best idea of its nature will be given by a list of the contents of the first number: The Rise and Progress of the Society; Eccentric Turning; Mensuration and Enumeration of the Impalpable and Invisible; Medallion Machine; Fancy Turning in Box-wood; and Breechloading Fire-arms. Several of the articles are illustrated.

THE December number of the *American Entomologist and Botanist* completes the second volume, and the publication will now be suspended for a twelvemonth, intending to be renewed again after that period. In the meantime the botanical editor, Dr. Vasey, will conduct a botanical department in the *Journal of Agriculture*, published at St. Louis.

THE Natural History Society of Montreal has just issued its Annual Report, comprising a sketch of its proceedings for the year ending May 1870. Although the number of members has decreased during the year, the Society has, nevertheless, shown considerable activity, and many valuable papers have been read at its meetings on Geology, Zoology, and general subjects, some of which have appeared in the *Canadian Naturalist*, the organ of the Society. A very important work is now contemplated by the Society outside its immediate sphere of action, viz., the dredging of the Gulf and River St. Lawrence. Application has been made to the Dominion Government for a free passage for the dredgers in one of their ordinary cruisers. It is feared, however, that this application may not be successful, and that the Society may have to draw upon its private resources for the necessary expenses.

THE *Homeward Mail* gives reports of the earthquake that was felt in Scinde in October last. On October 28 two shocks are reported from various places. One report says "the earth quaked for fifteen minutes from east to west, and the people felt sea-sick while the pitching continued," and another ascribes it to the fact that the dwellers in Upper Scinde must have specially incurred the displeasure of the gods.

HEAVY rains, followed by severe frost, have produced their usual effect in altering the shape of the land. We have accounts of two extensive landslips, one at Whitby and one at Mevagissey in Cornwall. At the former place, "a large part of the cliffs, supporting twelve houses, has fallen into the harbour, and it is feared that more will fall." At the latter place about 500 to 600 tons of rock were precipitated to a depth of fifty feet, and much damage was done. Exactly a year ago, in December 1869, a great landslip was reported near Nantmel in Radnorshire. The mass of earth which fell was of enormous size, and did not become stationary till it had travelled half a mile. Much damage was done, though no lives were lost.

DR. HENRI VAN HEURCK publishes in French, under the title of "Observationes Botanicæ et Descriptiones Plantarum novarum Herbarii Van Heurckiani," the first fasciculus of a description of new and undescribed species contained in his herbarium. The descriptions are drawn up by several eminent botanists, and the herbarium, one of the richest in the world, containing collections from all quarters of the globe, results from a fusion of those of Sieber, Baron von Reichenbach, and Dr. Van Heurck, to which numerous important additions have been made by purchase and otherwise. The volume is offered in exchange for other botanical publications.

DR. L. PFEIFFER of Cassel, has recently published the first part of a "Synonymia Botanica locupletissima Generum Sectionum vel Subgenerum ad finem anni 1858 promulgatorum." Such a synonymy is much wanted by botanists who may be working at any particular order or genus. The value, however, for the ordinary systematist, is considerably decreased by the adoption of the singular arrangement of Endlicher in preference to those in use in Hooker and Bentham's "Genera Plantarum" or in De Candolle's "Prodromus."

MR. THOMAS MEEHAN read a paper before a recent meeting of the Academy of Natural Sciences of Philadelphia on the Compass Plant (*Silphium laciniatum*). He confirms the statement of earlier observers, that when the plant first comes up, and until the leaves become large and heavy, there is an unmistakeable tendency towards the north. When, however, winds and rains have once borne them in different directions, they have no power of regaining the points lost. Hence the statement made by some, that they have examined the plant in its native habitat, and found no such tendency.

THE *Pharmaceutical Journal* for December 31st contains an interesting article on the trade in leeches. The annual value of the leeches imported into this country decreased from 27,068*l*. in 1853 to 7,067*l*. in 1869; the largest quantity coming formerly from Hamburg, but more recently from France. These figures probably represent an import at the present time of two million leeches annually, besides the home supply. The leeches annually employed in France may be taken at thirty millions, the largest portion being produced at home. The South and West of France and North of Africa still produce enormous quantities.

A farmer in the neighbourhood of Bordeaux has recently converted waste land worth 300 francs per annum into enclosures for leeches, which now bring him in 25,000 francs annually. Besides the well-known brown and green leeches, a communication to the Société Zoölogique d'Acclimatation of Paris, by M. de Filippi, describes a new genus, *Hæmentaria*, from Mexico and the Amazon, which possesses the valuable property of leaving no mark on the skin to which they are applied; acting not by biting but by suction.

An interesting paper on the introduction of Maize into China, by Dr. Hance and Mr. W. F. Mayers, appears in a recent number of the *Pharmaceutical Journal*. The authors are inclined to believe that Asia may rank as a native country of this cereal; "the remote date assigned by Chinese records to its introduction, and the circumstance that the introducer is unknown," being, in Dr. Hance's judgment, "irreconcileable with the supposition that it was brought to this country by the Portuguese, their first arrival here under Ferdinand Perez d'Andrada being in 1517, and the earliest notice of maize in European literature dating later than 1530. Mr. Mayers gives translations of passages from Chinese authors bearing upon the subject, as well as facsimiles of early Chinese engravings of the maize and millet.

Mr. Edward Newman, in the *Field* for December 31, directs attention to the fact that during 1870 there has been an unusual immigration of quails to this country, and that a still more unusual number have stayed to breed; and desires to acquire materials for what he terms "a census of quails" during this exceptional year. The statistics particularly desired are: The number of quails bagged, and the dates; the number of nests found; the number of eggs in each nest; and especially remarks as to the period and direction of flight, both on the arrival and departure of the migrants. The occurrence of the quail in Britain in such unusual numbers is, as Mr. Newman observes, a matter of great ornithological interest.

Much good would accrue to our peasantry and working classes generally, if a better knowledge of the value of Nature's products were diffused amongst them. Blind prejudice prevents the proper application of a host of "unconsidered trifles." We in England might take a lesson from what is done in Sweden by a Public Society, who, during a time of scarcity of food, and for the purpose of diffusing a knowledge of the edible Fungi and Lichens of that country, prepared, published, and distributed to the public schools no less than 10,000 copies of a pamphlet on the Fungi illustrated with coloured figures, and 4,000 copies of one on Lichens illustrated by actual specimens.

That the *Boehmeria nivea*, or China Grass fibre, will, ere long, become a regular article of import to this country, is highly probable, both from the fact of the recent reward of the Indian Government for the invention of machinery suitable for its cleaning and preservation: and from the nature of the plant being such that the climate and soil of many of our colonies are quite suited for its culture. There is no doubt that it is well adapted for a variety of uses, and could, by careful preparation, be applied to purposes for which our present commercial fibres, though to some extent used, are nevertheless unsuited. The Chinese bestow an immense amount of care and labour upon its preparation, hence the very fine fabrics which are produced in that country. In Sumatra, also, much care is given to its cultivation and preparation: the stems are usually cut when they are about six feet high. They are sometimes allowed to dry before the fibre is taken from them, but the most common practice is to take it as soon as the stems are removed from the ground. A viscid gum is found on the stem which, in Macassar, is scraped off and used as a mild sort of arrow poison. In China three crops of the stems are usually obtained in one year, but the second crop is considered to yield the best fibre.

*ON THE GEOLOGY OF NOVA SCOTIA**

The author, in treating on the Laurentian Rocks of Arisaig, Nova Scotia, discovered by him in 1868, referred to the occurrence of pebbles of diorite, syenite, and granite in the conglomerates of the Lower Carboniferous area of the townships of Arisaig and Antigonish, and the highly micaceous character of their grits and sandstones. He had experienced difficulty in accounting for these appearances. It appeared singular, especially, that the mica seemed to increase in those strata in proportion as they became removed from known granites. The lithological character of the discovered Laurentian band appeared to account satisfactorily for the occurrence of those constituents of the Lower Carboniferous strata. There are some gneisses and porphyritic diorites; hornblendic rock in great variety; serpentines, black quartzite strata with veins of quartz, with abundance of crystals of mica (some would be disposed to call them granite veins); white syenite with stripes of green felspar and red syenite, both very sparingly hornblendic. South of these lies a Carboniferous area which seems to overlie the Laurentian band unconformably. This area is bounded on the south by a subtriangular band of metamorphic Arisaig, or middle and upper, Silurian rocks. This band is disposed in two anticlinal folds with an intermediate synclinal. The author designates it the Antigonish Sugar-loaf Band, so named from a prominent mountain of 710 feet elevation. The extreme breadth of this band, *i.e.* N. and S., is about five miles. The axes run easterly and westerly. The S. side of the Carboniferous area referred to rests unconformably on the N. side of the northern anticlinal, the strata in contact being Lower Carboniferous conglomerates. This area extends to St. George's Bay and Cape St. George on the Gulf of St. Lawrence; it is basin-shaped, and is said to contain seams of coal. This area may be called the Arisaig area. South of the Silurian area lies the Antigonish Carboniferous area. The lower part of this area consists of conglomerates, limestone, and gypsum. The conglomerate lies unconformably on the Silurian slates of the S. side of the southern anticlinal. The slates dip $< 55°$ S. 5 E.; the Lower Carboniferous conglomerates and limestones dip $< 30°$ S. 35 W. The observations made are at variance with two theories that have been advanced by different geologists to the effect—1st, that the Upper Silurian and Devonian formations of Nova Scotia have been thrown into a few *great* folds, synclinal and anticlinal; 2nd, that the Carboniferous and underlying Devonian or Upper Silurian formations acquired their present positions simultaneously, the mountains having had a thick Carboniferous saddle, which had been subsequently removed by denudation. This theory supposes that the Carboniferous areas of Nova Scotia had been once united with each other and those of other countries. The Nova Scotia areas that are now separated have always been so, the only connection ever existing having been merely geological.

The author discovered an interesting outcrop of Laurentian syenite in the Silurian area. This forms, in conjunction with limestone, a noticeable hill of 300 feet elevation, in the middle of the Antigonish area of Carboniferous limestone and gypsum. This syenite is seen to a large extent in direct contact with limestone of Lower Carboniferous age, having abundance of cyrtoceras, conularia, dentalium, and *Leperditia okeni*. The limestone and its fossils have not been altered by contact with the syenite, showing, as a consequence, that the syenite had its existing constitution when the limestones were formed upon it in the bottom of the sea of the Lower Carboniferous era. A specimen from the summit of the hill in the collection of rocks in the Provincial Museum is reddish, like specimens in the same collection from the Arisaig Laurentian rocks. It is more hornblendic, and shows green mica, like that of a specimen of granite from a mountain in Baddeck, Cape Breton. The author made interesting observations on supposed Laurentian rocks in the Island of Cape Breton, which lies to the N.E. of Nova Scotia, being separated from the latter by a narrow strait called the Gate of Canso. In the Nova Scotia department of the Paris Exhibition of 1867, there was a specimen of serpentine from a rock at St. Annez, Cape Breton. Prof. Wyville Thomson detected in this specimen supposed eozoönal structure. The author lately received specimens of granite from White Head, Aspy Bay, Cape Breton; and also from a position seventeen miles S., and seventy-three W. from White Head. He also referred to the existence of auriferous slates, like those of Nova Scotia, at Middle River,

* Abstract of a paper read before the Nova Scotian Institute of Natural Science by the Rev. D. Honeyman, D.C.L., F.G.S., &c., Professor of Geology in the Provincial Museum.

Cape Breton. He observes that, if a line were drawn from the granite mountain at Big Baddeck already referred to, bisecting the granite district at Aspy Bay, the Middle River gold-field would be five miles distant from the line on the one side, and the St. Anne serpentine (eozoönal ?) three miles distant from the line on the other side. Here we have what is supposed to be Laurentian serpentine, granite, and auriferous argillite in no respect different from the argillite of Wine Harbour and other gold-fields of Nova Scotia, all in close conjunction. The existence of Laurentian eozoönal serpentine in this locality is in accordance with a *forecast* of Dr. Sterry Hunt, to the effect that a line from the Arisaig Laurentian to Newfoundland will pass through Cape Breton. We may now expect, he observes, to find limestone with eozoön there; and, on the contrary, the same facts appear to be at variance with his "Terra-Novan" theory. As the local name Arisaig has been applied by Dr. Dawson to the Middle and Upper Silurian of Nova Scotia, the author would suggest that, as Cape Breton appears to be *in a manner* the meeting place of the Laurentian of Arisaig, Nova Scotia, and the granites and argillites of the Nova Scotia gold-fields, the local term "Cape-Bretonian" should be adopted as their designation, and that "Terra-Novan" should be reserved for other countries. The one term is equally euphonic with the other, and much more ancient. It was observed that there was a great gap between the Laurentian of Arisaig and its Middle and Upper Silurian and Devonian. In searching for formations to fill the gap, it was necessary to look to the gold-fields of Nova Scotia. The evidence of fossils was much desiderated in the investigation. The grits and argillites of the gold-fields were lithologically different from the Middle and Upper Silurian and Devonian (fossiliferous or metamorphic), and stratigraphical evidence showed what the author regarded as constructive unconformability. He expects in the further prosecution of investigations which are to be recorded at a subsequent meeting of the Institute, to be able to bring the evidence of fossils indirectly to his aid, and to point out direct sequence. It was observed that the upper and middle Silurian rocks of Nova Scotia had as yet failed to show gold even in the very smallest quantity—that various localities having metamorphic slates and quartz-veins of Clinton or Middle Silurian age had rece ived a short-lived celebrity in the provincial newspapers, but the report had invariably been found incorrect. The author hailed the decisions of Prof. Hind in reference to the age of the Greneid (granite) grit and argillite of the gold-fields, and considered that he had rendered very important service in completing the Azoic (or Eozoic) and Palæozoic systems of Nova Scotia.

LETTERS FROM CENTRAL AFRICA*

SERIBA GHATTAS IN DJUR, *July* 29, 1870

AFTER an absence of nearly eight months I have arrived here once more, considerably reduced in bulk in consequence of the privations and fatigues which I have had to undergo, but otherwise thoroughly well and active. A poultry yard and a milch cow, which I intend to provide myself with, will, in addition to a few weeks' rest, restore my lost strength completely. The journey to the Niam-Niam country, which I undertook as the guest of my friend, Mohammed Abu Tsammat, with his ivory caravan of 300 men, and whose acquaintance I made during the river journey, was successfully completed, as we had no losses to deplore, except a few female slaves who were taken away whilst fetching water; and besides the wounding of the leader, Mohammed, only one of my people was injured by an arrow, which struck him in the arm, but fortunately the wound was speedily healed.

The climate of the country traversed by us is an exceedingly salubrious one, and my people as well as myself enjoyed the best of health. I had only reason to complain, and that bitterly, of two things, viz. the numberless, excessively tedious, and disagreeable passages across the rivers, rivulets, and swamps, and the want of a sufficiency of food, which I experienced during the whole of the journey. In the southern part of my route such passages occurred every quarter of an hour, taking sometimes hours to complete. My donkey, which I have brought back in thorough good health, was consequently of little or no use to me, as I should have had to dismount continually. The waters are here, contrary to the otherwise steppe-like character of the country through which we journeyed, invariably surrounded and overshaded by dense masses of trees; a small footpath leads through the thicket; broken boughs and stems of trees from three to four feet thick lie about in all directions, over which it is necessary to clamber or stumble. Wading up to the hips in the black mud of the swamp, and at the same time passing through the prickly bushes, especially the Pandanus and Kotany (Calamus or bamboo) which fetched blood at every step, I was unfortunately not able, like Speke, to take my clothes under my arms, as the hands were as essential as the feet in helping one forward. My large hat was my only clothing. At length, when I had crossed over, clean water had to be sought for ablutions; then when I had got rid of the black tint, which made me look like a moor, I had frequently to remove leeches, of the thickness of one's finger, which had fastened themselves to my legs. How greatly I regretted not being able to dispense with my trousers, at least, to avoid the excessive annoyance which the constant dressing and undressing caused, but the sensitive epidermis of the adult European does not so easily accustom itself to the roughness of the path, and the sudden changes in temperature require to be guarded against as carefully as a Russian summer does.

Our dietary arrangements were, as I have already hinted, but of a very moderate character. Amongst the real Niam-Niam people there was, it is true, durrah corn, and upon the outward journey there was abundance of root-vegetables, such as cassavi, colocasia, and admirable yams (on the return journey, unfortunately, all these had been devoured or returned to the earth); but, on the other hand, there was an utter absence of cattle, the only flesh that could be obtained being that of fowls. At King Munsa's there were goats, but no corn. If I had not occasionally found time for hunting—in which, upon my return journey, I was successful in meeting with large numbers of antelopes—I must have starved. This want of provision was the more keenly felt, through the constant partial immersions sharpening the appetite; and on account of the difficulties of the march we were only able to have one meal a day, so that one's stomach was never thoroughly satisfied. My butter, which I had exhausted, I was compelled to substitute with goat-fat, and later on even with oil. Fortunately I always preserved a stock of tea and salt.

I travelled from here to Seriba Sjabbi, several days' journey to the south-east. After travelling for days through nothing but desert, we reached the territory of the principal chief of the Niam-Niams, called Nganji, with whom Abu Tsammat stands upon a friendly footing. Farther on, we passed through a district which is quite under the subjection of the latter, and governed by a former Niam-Niam soldier placed there by him. A Seriba and thirty warriors suffice to maintain his authority in this tolerably populous district. From here we traversed the country under the rule of the powerful chief Uando. Notwithstanding threatening rumours, we found him peaceably inclined, and he offered me as a present a large pot containing the entrails of an elephant a hundred years old, which my people, to whom I handed the delicacy, assured me was very tough and rather high. After passing through another desert for several days, we reached the territory of the Mombuttu King, Munsa, whose residence was the most southern point reached by me, situated a little beyond the third degree north latitude. The southern part of it lies on the great Uelle river, which appears to me to be the upper Chari, flowing into the Tschad lake, and which resembles the Blue Nile, near Chartum.

I could fill volumes were I to relate all my experiences at the court of this wild brown Cæsar, covered all over with red copper spangles, and looking like a well-furnished kitchen; of his numerous wives, painted in all the colours of the rainbow; of his immense palace, resembling a railway station, one of the rooms of which, and where I was first received, being 100 feet long by 50 feet broad, and 40 feet high. It would be impossible for me, however, to pass over in silence the horrible cannibalism which is here, as well as among the real Niam-Niams, everywhere in vogue. Munsa dines off human flesh every day of his life; the Mombuttu people make regular battues upon the wilder negro races in the south, where those that are killed are at once cut up, the fat is melted down, and the flesh dried. Those that are captured are driven off to be slaughtered at convenience.

The Niam-Niams are thrown more upon their own resources. If, however, there should happen to be a cessation of internecine feuds, they attack the Nubian caravans, although it should be to their interest to keep the peace, as they are well paid for their ivory and provisions with copper and glass beads, and their

* Translated from the *Cologne Gazette.*

chiefs receive rich presents. It is true the Nubians are not so philanthropic in their seribes, but in respect to the Niam-Niams, nothing can be said against them, as hostilities would destroy the object they have in view. The buried ivory cannot be discovered by any divining rod; there are no cattle to be stolen; and the women and children always hide themselves at once, and in time, in the impenetrable thicket of the woods, so that no booty is to be obtained in slaves. It is, therefore, however improbable it may sound, the Niam-Niams who, entirely through their horrible lust for human flesh, commence the war. "Flesh, flesh!" is their war-cry, and a few female slaves, at least, who have lost their way in fetching water, are sacrificed to their cannibalism.

The journey back was commenced by the same route. On touching upon Uando's territory once more, alarming rumours reached us. It was said that this chief had brought out the whole of his force of warriors to bar our passage; in fact we discovered that the first villages we came to were deserted; armed Niam-Niam warriors lurked everywhere in the tall grass, and approached within range of our guns. But they did not show themselves particularly desirous of entering into hostilities with us. At one of the next villages, where Abu Tsammat received from the head man some ivory which he had left behind him upon the outward journey, several Niam-Niam men pressed their services upon us as guides or parlementaires. I was fully convinced of the existence of treachery, and vainly endeavoured to persuade Mohammed to seize some of these spies, and hold them as hostages. He had to repent it bitterly. After a short time they proved themselves to be assassins sent out by Uando, as the chief fondly imagined that the caravan would fall into his possession upon the death of the leader. Mohammed rode in front upon his mule; close behind him came the Niam-Niams. I followed a few paces behind them, and carried my gun myself, whilst Mohammed, according to custom, had his carried after him All at once I heard shots, and saw Abu Tsammat fall from his saddle covered with blood. One of the Niam-Niams had given him a thrust with his spear; the assassins made off, and were lucky enough to escape, notwithstanding the shots that were sent after them, as there could be no question of pursuing them into the thicket. At the next village halt had to be made for the purpose of rest. The place was almost entirely in flames, and an entrenchment was made from the *débris* of the houses. Fortunately, the wound of the leader of the caravan, although a very severe one, it having been increased by drawing out the barbed point of the spear, was not very deep. With a number of entomologist's pins which I happily possessed, I managed to sew it up, and in three days' time the wound was nearly closed, and would have been soon completely healed if Mohammed could have kept himself quiet. During our enforced stay at this place we were frequently alarmed by demonstrations on the part of the enemy, but they could not summon up resolution to attack us seriously.

Busier times soon followed. The most serious part of the journey was the passage across the rivers, which, although we now followed a more easterly direction in order to avoid several of them, was occasionally used by the Niam-Niams for an attack upon us. The noise and shouting may well be imagined, when for instance a female slave completely disappeared with her burden in the flood, the beating of the Nubian soldiery, the clatter of the pumpkin shells and kettles; all this increased by a hail of arrows hurled by unseen hands from the adjacent thickets. However, we passed through without any loss; the enemy did not venture upon approaching near enough to hurl his costly iron projectiles, but contented himself with bamboo arrows with heads of hard wood. Another division that was allied to us, but which had separated itself from us on the outward journey, was not so fortunate, as whilst it was endeavouring to join us upon the return journey, it was attacked during the passage over the river by an overwhelming force. The leader and several of the soldiers were killed outright, others were severely wounded, so that the company was compelled to leave many valuable articles behind, in order to get out of the swamp as quickly as possible, and thus secure its retreat. After a very fatiguing march, I thus at length reached Seriba Tsabbo once more, where I intend resting for some weeks to recruit my strength, and to complete my collections and correspondence. Upon the road I had to cross once more the river Tondji, the passage of which I have made so frequently. As there is an utter lack of boats, all the baggage has to be conveyed on little rafts, each of which is steered by a swimming negro across the raging torrent. I can only express satisfaction with the result of my journey, although the direct distance travelled was not very great, being from here to Munsa's town about seventy-five German miles. I became acquainted with races, which, until very recently, had never come into contact with European and Oriental civilisation in the slightest degree, and who had developed for themselves a perfectly independent state of cultivation, so strange and uncommon that one imagined himself in a new world when among them. Not a scrap of European clothing, not a single glass bead remains with Mombuttu to remind one of the connection opened up by Mohammed Abu Tsammat a few years ago. Extraordinary to relate, there was no trace whatever to be found there of the great lake mentioned by Piaggia, and previously by von Heuglin, although we met with various tribes of the Niam-Niams, and were well supplied with interpreters. I have naturally laid down my route carefully, have made a collection of words of the different languages spoken by the races visited by me, and have taken the dimensions of numberless individuals, amongst others, several of the Acku dwarfs, whom I met at the court of Munsa, and one of whom I took away with me as my faithful attendant. The remains of the Mombuttu feasts furnished several skulls for my collection. The booty in plants was also a very extensive one. I have made up my mind, upon important grounds, to remain here for another year, and to make another journey into the Niam-Niam country, but this time by a westerly route, in order to clear up several remaining doubts as to the geography of this country, which was never traversed before me by a single European.

G. SCHWEINFURTH

SCIENTIFIC SERIALS

Poggendorff's Annalen, 1870, No. 8—The following are the contents of this number: (1) "Thermochemical Researches" (sixth, seventh, and eighth parts), by Julius Thomsen. This forms the conclusion of Thomsen's researches into the thermal effects of the neutralisation of acids, and ends with a collective statement of results. The experiments relating to what the author calls chemical "avidity" are likely seriously to modify commonly-received views of chemical action, showing as they do that the heat of combination between acids and bases is not a measure of their tendency to combine. (2.) "Researches relating to Electrical Discharge," by W. von Bezold. Experiments relating to the propagation of sudden electric waves in branched conductors. The author finds, among other results, that the velocity of such waves is independent of the material of the conductor; his experiments also indicate the existence of electrical phenomena analogous to the reflexion and interference of waves. (3.) "On the Electro-motive Force of the Voltaic Arc," by W. von Bezold. Edlund has shown that the electric light plays the part, not merely of a resistance interposed in the circuit, but also of an inverse electro-motive force. Von Bezold attempts an explanation of this fact, founded on the consideration that the discharge between the carbon-points must be periodic instead of continuous, and therefore their difference of tension a variable magnitude, whose maximum exceeds the electro-motive force corresponding to the resistance of the arc and the mean strength of the current. (4.) "On the Theory of the Electrophorus Machines and of the Supernumerary Conductors," by P. Riess. (5.) "On the Specific Heat of Water in the neighbourhood of its maximum density," by L. Pfaundler and H. Platter. The authors determined the specific heat of water between 0° and 11° C. by mixing weighed quantities at known temperatures between these limits, and observing the temperature of the mixture. From their results, they calculate an empirical formula containing the fourth power of the temperature. Taking the specific heat at 0° as 1, they find that at 1°·25 it is only 0·9512, while at 6°·75 it is 1·194, and at 11° it is again as low as 1·0298. (6.) "Acoustical Studies of Flames," by E. Villari. The author found that the tone of a vibrating tuning-fork was reinforced when brought near to a large gas-flame. When the flame, which was thus thrown into sympathetic vibration, was looked at through radial slits in a rapidly revolving opaque disc, it was found that, if the rate of rotation of the disc bore the proper relation to the rate of vibration of the fork, the flame appeared to be divided by stationary bands showing alternate maxima and minima of brilliance. When the rate of vibration was changed, but all other circumstances remained unaltered, the distance between the bands was found to vary inversely as the rate of vibration. (7.) "On the ratio of transverse contraction to longitudinal extension," by Heinrich Schneebeli. The author has applied Kundt's mode of measuring the length of stationary waves to the comparative measurement of the rates of the torsional and longitudinal vibrations of steel rods, and hence to the determination of the ratio between the transverse contraction and longitudinal extension produced by stretching forces: the mean results agree closely with those obtained by Kirchhoff and Okatow, as well as by Everett (Phil. Trans. 1867), from experiments on flexure and torsion. (8.) "On the compensation of an optical difference of path," by J. L. Sirks. An investigation of the condition under which the interference tints produced by polarised light passed through a thin plate of crystal can be achromatised by a compensating plate of selenite. (9) "Rejoinder to Dr. Most," by L. Boltzmann, relates to the second law of thermodynamics. (10.) "A contribution to the doctrine of Molecules and to the theory of Electricity," by C. Lorenz. An attempt to calculate the absolute number of molecules in a milligramme of water, founded upon Weber and Kohlrausch's absolute measurement of the electro-chemical equivalent of water and on the difference of potentials required for its electrolysis. (11.) "A contribution to the theory of Terrestrial Temperature," by O. Frölich. A discussion of Poisson's expression for the internal temperature of the earth at small depths below the surface, as a function of the time and the superficial temperature. (12.) "Remarks on the 'Bohemian Diamond,'" by Prof. V. L. von Zepharovich. The author states that only *one* diamond (not several, as has been implied in some reports) has been found in Bohemia; that this was discovered in a workshop in Dlaschkowitz, where pyropes (garnets containing chromium) are ground and bored with the help of diamonds; and that it is not yet ascertained how it came to be among the pyrope-sand in which it was found. (13.) "A remarkable stroke of Lightning," by Dr. J. G. Fischer. By examining the position of the magnetic poles in various pieces of iron and steel which were magnetised by the passage of the discharge, the author ascertained that the direction in which the negative electricity passed was downwards into the ground. (14.) "On the ratio of the specific heat of air at constant volume to its specific heat under constant pressure," by Dr. Witte. The author concludes, on experimental and theoretical grounds, that this ratio is not constant, but is a function either of the temperature, or of the pressure, or of both. (15.) "On the minimum of prismatic deviation," by A. Kurz. (16.) "An easy mode of preparing a liquid for the production of Plateau's Equilibrium-figures without weight," by Rudolph Böttger.

The *American Naturalist* for December opens with a paper on the Flora of the Prairies, by Mr. J. A. Allen, in which he gives an interesting sketch of some of the peculiarities of the primitive flora of the Upper Mississippi prairie in northern Illinois, and central and western Iowa, not inaptly termed "the Garden of the West." He remarks that the breaking and turning of the soil at once exterminates a number of the previously dominant species, and instead of lingering as troublesome weeds, the more hardy exotics that through man's influence assume an almost cosmopolitan habit, usurp their places, the cereals, the cultivated grasses, and the noxious weeds of the old world, thoroughly crowding out the original occupants of the soil. Dr. W. Stimpson follows with an article on the Distribution of the Marine Shells of Florida; and Mr. A. S. Packard with one on the Borers of certain Shade trees. Spring time on the Yuron, by Mr. W. H. Dall, gives an account of the sudden advent of summer in that territory. Mr. A. S. Collins on the Impregnation of Eggs in trout-breeding will be interesting to pisciculturists in this country, explaining the principle of a new process pursued at the trout ponds in Caledonia, N.Y. The usual space is devoted to reviews and miscellaneous intelligence, and we have some further details of papers read at the Troy meeting of the American Association.

The *Journal of Botany* for January has increased the amount of its contents by a rearrangement of its type, without any corresponding increase in price. We are glad to observe that it is intended to devote the journal more exclusively in future to British botany, thus supplying a want long felt by workers in this department. In the present number there are several articles of interest, including a description (with plate) by Mr. Worthington Smith, of a new species of fungus gathered in Messrs. Veitch's cool fernery at Chelsea; Observations on the genus *Pottia* (of Mosses), by Mr. W. Mitten; a few notes on Mr. H. C. Watson's Compendium of the "Cybele Britannica," by the Hon. J. L. Warren; and a Monograph of the genus *Xiphion*, belonging to Iridaceæ, by Mr. J. G. Baker. There is also a useful epitome of Dr. M'Nab's important paper on the "Transpiration of Aqueous vapour by Leaves," to which we have already referred; and the column of short Notes and Queries will be found interesting and valuable.

SOCIETIES AND ACADEMIES

London

Zoological Society, January 3. — Professor Huxley, F.R.S., V.P., in the chair.—Prof. Flower exhibited and made remarks on a mounted skull of the Common Sturgeon (*Acipenser sturio*), from the Museum of the Royal College of Surgeons, in which the cartilaginous portions had been replaced by a wooden model. — Mr. Tegetmeier exhibited and made remarks on a specimen (in the flesh) of a female of the Great Bustard (*Otis tarda*), which had been killed on the 29th ult. near Feltham, in Middlesex.—Mr. Gould exhibited and made remarks on a skin of Lady Rosse's Touraca (*Musophaga rossiæ*), just received in a collection of birds from Loanda.—Mr. Wallace read some extracts from letters received from his brother, Mr. J. Wallace, containing remarks on the habits of a species of Lizard (*Phrynosoma*) and Rattlesnake (*Crotalus*), as observed in California.—A tenth letter was read from Mr. W. H. Hudson, on the ornithology of Buenos Ayres. — A letter was read from Mr. E. P. Ramsay, giving particulars respecting the habits of the new Australian Mud-Fish (*Ceratodus Forsteri*).—The Secretary read extracts from some correspondence between himself and Mr. G. W. des Vœux, Administrator of the Government of Santa Lucia, as to the best method of destroying the Poisonous Serpents (*Craspedocephalus lanceolatus*) found in that island.—Mr. Sclater exhibited and made remarks on the horn of the male Rhinoceros, which that animal had torn off in the Gardens on the 10th August last.—Mr. Flower read some notes on the skeleton of the Australian Cassowary (*Casuarius australis*), in which the differences between the skull of that species and *C. galeatus* were pointed out. Mr. Flower's observations were based on the skeleton of this bird, transmitted to Mr. Sclater by the Messrs. Scott, of the Valley of the Lagoons, Queensland, aud now in the Museum of the Royal College of Surgeons.—A communication was read from Mr. Andrew Murray, containing some notes on the structure of the young of the Sterlit (*Acipenser ruthenus*).—A communication was read from Mr. George French Angas, containing descriptions of thirty-four new species of shells from Australia.—A joint communication was read from Dr. G. Hartlaub and Dr. O. Finsch, on two collections of birds from the islands of Savai (Navigator group) and Rarotonga (Hervey group). Several new species were described in this paper, the most remarkable of which was a new form, allied to *Gallinula*, from Savai, proposed to be called *Pareudiastes pacificus*.

Geological Society, December 21. — Mr. Joseph Prestwich, F.R.S., President, in the chair. "On Lower Tertiary Deposits recently exposed at Portsmouth," by C. J. A. Meyer, F.G.S. The author described some exposures of Lower Tertiary deposits made during excavations for the "Dockyard Extension Works" in Portsmouth Harbour. The thickness exposed, exclusive of alluvial deposits, amounted in all to 127 feet. The beds dip S.S.W., or nearly south, $2\frac{1}{2}$ to 3 degrees. The author grouped them under the following divisions, in ascending order:—

1. Clays and sands with pyrites, 36 feet.
2. Argillaceous sands with *Dentalium*, 25 feet.
3. Sands with *Lingula*, 8 feet.
4. Clays with *Cyprina* and sandy clays, 55 feet.

The author indicated the fossils contained in each of these divisions, remarking upon the range of some of the species, and upon the apparent mixture of London clay forms with others usually regarded as characteristic of higher or lower beds which occurs especially in the "*Lingula* sands." He suggested that, as the species found here present some slight differences from those occurring in other deposits, the difficulty might be got over on Darwinian principles. The author considered that the fossils did not furnish any satisfactory evidence of the true position of these beds; but, from stratigraphical evidence, he regarded them as being included in group 3 and part of group 4 of Mr. Prestwich's section of the Whitecliff strata in the Isle of

Wight. He concluded with some remarks on the superficial deposits consisting of gravel and old and recent mud overlying the Tertiary beds in the section described by him. Prof. Ramsay called attention to the value attaching to such observations as those of the author on the nature of the superficial deposits.—Mr. Etheridge observed that the presence of the *Lingula* determined the position of the Bognor beds in the series, though there appeared great difficulty in fixing it stratigraphically. The commingling of species exhibited in this instance of shells hitherto supposed to be peculiar to certain horizons, he regarded as very remarkable.—Prof. Morris observed that the section seemed to show, not only the order of the beds, but their manner of deposition, the whole having formed part of a tranquil sea-bottom. He remarked on the difficulty of separating the more recent mud deposits from the beds of more ancient date. He pointed out the method of formation of septaria apparently by segregation, as they sometimes included undisturbed parts of the beds. The number of bivalves bored by carnivorous mollusks was remarkable, as was also the absence of *Pectunculus*. —Mr. Gwyn Jeffreys observed on the habits of *Lingula*, which had been by some regarded as an annelid, and not as a mollusk. It afforded a curious instance of the persistence of species, as there was no distinction that could be established between those of the Crag and of Silurian times. It lived at the present time between high and low water mark, and the *Panopæa* at a slightly lower level, and probably had done so in Tertiary times. Mr. Evans inquired whether the upper gravel, like that on the shore of Southampton Water, contained any flint implements. Mr. Meyer replied that he had not examined the gravels with that view.—"Note on some new Crustaceans from the Lower Eocene of Portsmouth, collected by Mr, C. J. A. Meyer, F.G.S." by Mr. H. Woodward, F.G.S. Mr. Woodward drew attention to the occurrence in the fossil state of pelagic forms of Crustacea armed with long spines on the latero-anterior angles of the carapace. Two Eocene forms had been described by Dr. Alphonse Milne-Edwards, namely, *Enoplonotus armatus* and *Psammocarcinus Hericartii*. Two new forms, differing generically from the above, but probably referable to the same family (the *Portunidæ*), were descibed, under the names of *Rhachisoma* (g. n.), *R. echinata*, and *R. bispinosa*. A third form, belonging to the Corystidæ, was then noticed. This family, represented in the fossil state by the genus *Palæocorystes*, is well known in the Gault and Upper Greensand of Folkestone and Cambridge, one species ranging up as high as the Maestricht beds. The occurrence of *Palæocorystes* in the Lower Eocene is of great interest. Mr. Woodward named this new *Palæocorystes*, *P. glabra*. 3. "On the Chalk of the Cliffs from Seaford to Eastbourne, Sussex," by W. Whitaker, F.G.S. — The author compared the chalk of the Sussex coast with that of the Kentish coast, and stated that it consisted of the following divisions in descending order :—

1. Chalk with flints of great thickness.
2. Chalk with flints and nodular layers, weathering rough.
3. Chalk without flints, but with nodular layers, weathering rough.
4. Thick-bedded massive chalk without flints.
5. More thinly-bedded chalk without flints, but with marly beds.
6. Chalk-marl, 50 or 60 feet.

The highest of these divisions stretches as far eastwards as Beachy Head, and forms the whole of the cliffs to within a short distance of that point. 4. "On the Chalk of the southern part of Dorset and Devon," by W. Whitaker, F.G.S. The divisions of the chalk were traced by the author westward from cliffs on the north side of Swanage Bay to beyond Beer Head in Devonshire. At first the succession of the beds was shown to be as in the Isle of Wight, namely :—

1. Chalk with flints, very thick.
2. Chalk with few flints.
3. Chalk-rock, very thinly developed.
4. Chalk without flints.
5. Chalk-marl.

It was shown that the lower beds became thinner westward, until, at one part of the Beer Head section, the chalk with flints rested at once on the Upper Greensand; and the following general conclusions were drawn :—That the chalk-marl thins westward, and its bottom part becomes marked by the presence of quartz-grains, showing perhaps signs of a less deep-sea character than usual. That the chalk without flints thins westward (from about 200 feet in the Isle of Wight), until, in Devonshire, it is but 30 feet thick, or even less. The consequent nearness of the chalk with flints to the Greensand helps to explain the deposits of flints on some of the Devonshire hills. Mr. Etheridge pointed out the resemblance between the series described by the author and that of the chalk of Antrim. He thought it probable that the cretaceous beds had originally extended over the whole of Western England. He called attention to the Blackdown-beds, which had been regarded as Upper Greensand, but certainly were not so, though probably Cretaceous, as well worthy of examination. Mr. Hull hoped that some Fellows of the Geological Society would extend their examination of the chalk into Ireland, and visit the Antrim district. It was the case there that the Chalk with flints rested immediately on the Upper Greensand, though there was an intermediate band known as the Mulatto-bed, which might possibly represent the Chalk-rock. Prof. Morris thought the paper afforded evidence in favour of the Chalk having been deposited in a sinking area, and during the process various alterations in the conditions took place. Mr. D. Forbes inquired as to the character of the nodules mentioned, and whether they were siliceous or not? Mr. Meyer mentioned that near Branscombe there occurred a band within eight feet of the Red Marl, containing fossils apparently the same as those of Blackdown. Mr. Whitaker had purposely avoided characterising the greater part of the Greensand-beds as either Upper or Lower. He thought the Cherty-beds of the west were stratigraphically higher than those of the Isle of Wight. The nodules inquired about were not siliceous, though probably containing some silica, but were rather phosphatic.

Anthropological Society, January 3. Dr. Charnock, V.P., in the chair.—Captain C. C. Poole, of Myansung, Pegu, was elected a Fellow. Professor Cav. Luigi Calvri, of Bologna, was elected a corresponding member.—Mr. Joseph Wilkinson exhibited and described a collection of human remains, weapons, and other works of art, found in an Anglo-Saxon cemetery near Barrington, Cambridgeshire.—Dr. Richard King read a paper on "The Manx of the Isle of Man." The author treated of the physical and psychological characteristics of the people of the isle, who, he maintained, were a pure stock of the great "Keltic" division of mankind; of their history, superstitions, language, literature, and works of art, and the statistics of population. On the latter, however, further information was required, which Dr. King hoped the census of 1871 might supply.—A paper by Dr. Beddoe, president, was read "On the Anthropology of Lancashire." The pre-historic antiquities of Lancashire are rather scanty, and the early and mediæval history of the north-west of England is remarkably barren as compared with that of the north-eastern district. The inhabitants of Salford were of Teutonic character, having been colonised during the Roman period by a cohort of Frisians, a few Danish, and other Scandinavian elements being present. The latter appear to be the strongest. The Saxon, or Angle, is in some force, as is also the Keltic, which, however, seems to have been partly Gaelic, and not wholly Kymric, as might, perhaps, have been expected. The effect of the Norman Conquest on the race elements in Lancashire would probably be inconsiderable, though there, as elsewhere, the Anglo-Danish, or Anglo-Norse, aristocracy, may have been somewhat more diminished, by slaughter and emigration, than the commonalty, whose blood may have had a larger admixture of the Keltic element.

Entomological Society.—Mr. Alfred R. Wallace, President, in the chair. Dr. Ross, of Toronto, was elected a member. The fourth part of the Transactions for 1870, published in December, was on the table. Exhibitions of British *Lepidoptera* were made by Mr. W. C. Boyd and Mr. Verrall; and of West African *Lepidoptera*, by Mr. Butler. A paper by Mr. Hewitson was read, entitled, "New Species of South American Diurnal *Lepidoptera*."

BRISTOL

The Observing Astronomical Society. — Report of observations made by the members during the period from August 6 to October 7, 1870, inclusive. (Continued from page 40.)

Aurora Borealis.—Mr. John Birmingham, of Millbrook, Tuam, writes :—"Though the night of the 24th September, when there was no moon and a densely cloudy sky, ought to have been extremely dark, it was, on the contrary, about as bright as if the moon were full, and the sky was similarly overcast. This extraordinary brightness began to decrease at eleven o'clock, and continued diminishing up till midnight, when the clouds cleared away, and revealed an Aurora Borealis of rare splendour, though it was doubtless inferior to what, unfortunately, the state of the sky prevented from being observed previous to eleven o'clock. The auroral arch was wanting, but long beams extended up from its usual position, and brilliant coruscations were flashing almost on every side to the zenith, even at times from the south. At precisely $0^h\ 40^m$ G.M.T. there was a well-defined corona, with its centre exactly at *Beta Andromedæ*. By means of a lamp held at some distance, with the aurora as a background, I was enabled to position three spectroscope lines with a small pocket instrument. These were the usual bright band in the green, a very faint one near it on the left, and one of medium brightness near F. On the night of October 14, during another remarkable display, when the intense red of broad areas of light did not seem enfeebled by the rays of a very bright moon, there was no indication of a red line in the spectroscope. In fact, there was here no line whatever to be detected, and the white light seen in some parts of the sky gave only the one principal line in the green." Mr. H. Michell Whitley, of Truro, reports that on September 21 he observed aurora-parallel streaks of a rosy hue reached to an altitude of about 30° fading away and reappearing in fresh position. On September 24 another aurora was observed by him. "At times the streaks almost reached Polaris. On the following night a repetition of the phenomenon occurred. He observed that the streamers, after fading and disappearing, would again appear in all their beauty in fresh positions, when the sky would glow like a furnace, lighting up the surrounding scenery, as if it were illuminated by the reflection from some distant fire. About $8^h\ 15^m$ a beautiful rosy beam enveloped Capella, whilst a fiery, glowing cloud lay a little to the east of it. At this time the display was at its maximum degree of splendour." Exhibitions of aurora were also observed by the Rev. S. J. Johnson, of Crediton, Mr. William F. Denning, of Bristol, and other members of the society.

Occultation of the Planet Saturn.—Mr. E. B. Knobel writes that this phenomenon was observed exceedingly well at Burton-on-Trent. "The disappearance occupied $1^m\ 10^s$. There was too much twilight for me to pick up Titan. The reappearance was observed to perfection, as far as atmospheric influences went, and, notwithstanding the low altitude, definition was very sharp as the planet emerged behind the bright limb of the moon. Ball's division, the shadow of the planet on the ring, and belt across the planet was quite distinct. The colour or rather the comparison between the colours of the moon and Saturn was decidedly different from that noticed at the April occultation. In consequence of low altitude, Saturn appeared of a light *liver* colour by the side of the yellow moon, whereas in April the colour of Saturn was more greenish. According to my rough observation, the time during which Saturn was *totally occulted* was $1^h\ 11^m\ 35^s$." The Rev. S. J. Johnson, of Crediton, reports that at $4^h\ 40^m$ he first observed the moon, but could not make out the planet before a quarter to six. "Saturn was then visible though somewhat faint, with a power of seventy on a 2¼in. aperture; with 150 it almost faded away in the field of view. The planet appeared very dull at its emersion." Mr. George J. Walker, of Teignmouth, witnessed the disappearance of the planet with a 2in. O.G., power 32. The Moon totally obscured Saturn at $5^h\ 45^m\ 45^s$, town mean time, which equals $5^h\ 59^m\ 44^s$ G.M.T. Mr. J. C. Lambert, of Sleaford, gives the following times of the disappearance of the planet and its ring:—First contact with ring, $6^h\ 4^m\ 2^s$; first contact with globe, $6^h\ 4^m\ 14^s$; disappearance of globe, $6^h\ 4^m\ 50^s$; disappearance of the ring, $6^h\ 5^m\ 6^s$.

Jupiter.—Mr. A. P. Holden, of London, writes: "The chief feature in the belt system of this planet has been the darkness of the permanent belt, which lies midway between the equator and the N. pole. Up till about the end of September it was so dark as to be readily visible with a very low power. Since then it appears to have brightened somewhat." Mr. H. Michell Whitley observed the planet on September 20, 11^h to $11^h\ 30^m$: "The equatorial zone is of the same copper colour as during the last opposition, and of quite as deep a shade. The streaks N. and S. of this zone pale yellow. The narrow sharply-defined belt N. of the N. yellow streak is of a finer tint than in the spring of this year, being of a fine purple grey, with a very perceptible tint of rose colour in it – N pole, grey. The narrow band S. of S. yellow streak not as fine a colour as the belt N. of N. yellow streak, being purple grey—S. Pole, grey."

The Nebula in the Pleiades.—Under very favourable atmospheric circumstances, Mr. Albert P. Holden, of London, has had a very careful search for this object with his 3in. refractor of very fine definition. He says: "Although favoured with good eyesight, I entirely failed to pick it up. Upon comparing the image of Merope, as seen in the telescope with that of the *lucida* of this group, a very perceptible difference was observable. The rings surrounding Merope were more numerous, and had a very misty, ill-defined appearance; they were also markedly extended in a direction N. of the star. With these exceptions not the slightest traces could be found of the nebula. It has been seen with only 2in. Webb saw it readily on October 6, 1863, but found it 'very feeble' on September 25, 1865. Any member of the society, working with a large aperture, would confer a favour by searching for this object."

Coggia's Comet.—This comet has been seen on several occasions by Mr. George J. Walker, of Teignmouth. On the 29th and 30th of September it was in the field with a large number of eight and nine mag. stars. "It looked like a tolerably bright globular nebula."

Manchester

Literary and Philosophical Society, December 27, 1870—E. W. Binney, F.R.S., President, in the chair. "Observation of the Eclipse of the Sun, December 22, 1870," by J. B. Dancer, F.R.A.S. The eclipse of the sun on Thursday, the 22nd of December, was favourably observed at Ardwick. Although a slight fog prevailed, all the details of the phenomenon were distinct, and tolerably well defined. A number of spots were visible on the sun's surface, two of which were of some magnitude. The nuclei of these spots were linked together by maculæ, and surrounded by a penumbra which extended to a considerable distance. Faculæ also were very numerous and distinct. The approximate times of contact taken by a chronometer corrected by the standard clock at the Town Hall were as follows:—first contact of the moon's limb with the sun $11^h\ 5^m\ 49^s$; Contact of moon's limb with nucleus of the first large spot, $11^h\ 31^m\ 36^s$; with the nucleus of the second large spot, $11^h\ 37^m\ 20^s$; last contact of moon's limb with the sun, Greenwich mean time, $1^h\ 37^m\ 3^s$. The temperature during the progress of the eclipse was taken at intervals by a mercurial thermometer with a black bulb *in vacuo*, exposed to the sun at the height of 4 feet from the ground.

TIME.			TEMP.
H.	M.	S.	DEGREES.
11	10	0	31·5
—	35	0	30·25
—	45	0	29·75
—	50	0	29·25
12	22	0	27·2
—	35	0	28·5
1	37	0	29·0

I had an impression that the moon's edge could be traced a short distance from the edge of the sun at the upper and lower points of contact, but this might be imagination. The black surface of the moon appeared very uniform in colour. I tried with powers of 80 and 180 to distinguish the moon's disc, but did not succeed. Light clouds were passing over the sun's disc at this time. The diminution in light was quite perceptible at the time of the greatest phase. Mr. Baxendell said that he observed the commencement of the Eclipse at Cheetham Hill. The first contact took place at $11^h\ 5^m\ 46{\cdot}2^s$ G.M.T. or 24·2 seconds later than the time calculated by Mr. Dickinson and Mr. Hind. The definition of the limbs of the sun and moon, and of the spots on the solar disc, was remarkably good, and he did not think his observation of the time of first contact could be in error to the extent of one second. The limb of the moon on the sun's disc appeared to be more sharply defined than the sun's limb. No distortion of the cusps was noticed. Unfortunately he was obliged to leave the observatory before the end of the eclipse, and therefore did not observe the time of last contact.

Edinburgh

Royal Society, December 19.—Dr. Christison, the President, in the chair. The following papers were read:—1. Additional Remarks on the Theory of Capillary Attraction, by E. Sang, Esq., C.E. 2. Laboratory Notes: On Thermo-Electricity, by Prof. Tait. An endeavour to prove, experimentally, that the electric connection of heat is proportional to the absolute temperature, and an application of this result to the measurement of high temperatures. (3 and 4.) Note on Linear Differential Equations in Quaternions, and Note on some Quaternion Integrals, by Prof. Tait. (5.) Note on an Ice Calorimeter, by Prof. Crum Brown. The author had, some years back, ordered the construction of an instrument on the same principle as that lately described by Bunsen. It is not yet completed, and he sent this note, not of course to claim priority, but to reserve to himself the right to use his own instrument.

Royal Physical Society, December 21.—Mr. R. F. Logan in the chair. The office-bearers for the session were elected as follows:—Presidents: R. F. Logan, C. W. Peach, Dr. Robert Brown. Council: James M'Bain, M.D., R.N.; Stevenson Macadam, Ph.D.; Andrew Wilson, Robert Scot Skirving, David Grieve, Professor Duns. Secretary: John Alexander Smith, M.D. Treasurer: Henry Budge, C.A. Assistant Secretary: James Boyd Davies. Honorary Librarian: Andrew Taylor. The Secretary exhibited the head of a roedeer, with the upper part of each horn bent backwards into a hook shape, or rather a complete loop; probably due to an injury when the horns were growing. He also exhibited a curious large specimen of a pigeon, with a bluish-grey head, mottled with white, and rest of plumage nearly white, the back and wings mottled wth a few darker feathers; tail large, nearly white; the breast and abdomen show traces of the reddish colour of the cushat, and the sides of the neck also showed the bright white spot, slightly bordered with green and red reflections, as in the cushat. It was shot in company with a flock of wood pigeons at Aldrught, near Elgin, in December, 1869. The bird has been supposed to be probably a hybrid between the cushat, or wood pigeon, and a fancy domestic pigeon, as a pouter, being rather larger in size than the cushat. If this were so, it is perhaps the first instance of the kind that has been observed; but probably a much more simple explanation may be given by considering it simply an albino cushat, or variety showing the plumage much changed to white. Very little variety occurs in the plumage of the cushat, so that the specimen is a rare one. The secretary also exhibited a specimen of the *Labrus mixtus*, or cuckoo wrass, taken on a long or hadock line in the Firth of Forth, in September, 1870. It is common on some rocky coasts, and specimens have been taken acording to Mr. C. W. Peach, at Wick, Iverach, and Kirkwa, in Orkney, but has apparently not before been recorded as taken in the Firth. The *Labrus trimaculatus*, or three-spotted wrass has, however, been taken oncee or twice in the Firth of Fourth; and, according to Dr. Günthr, in his valuable "Cataloge of Fishes," the latter is not a distinct-species, but simply the female of the *Labrus mixtus*.—Mr. Robert Brown, Ph. D., M.A., submitted some recent observa tions regarding the Arctic marine currents. The author considered that there, were three main currents, which traversed th Arctic, American and European seas, exclusive of those of Asiae and Behring Straits. These were:—1. The current sweeping out of the Kara Sea to the westward, getting deflected against the Greenland coast; sweeping down that coast at the averag rate of eight knots an hour, varying according to the season, doubles Cape Farewell, and then runs north along the western shores of Greenland, decreasing in rapidity and in breadth from about 100 miles, to which it stretches at Cape Farewell, until its force is exhausted at near Disco Island. This current jams up the eastern shores of Greenland, within which it is always on the move summer and winter, and as seen rounding Cape Farewell is known to Davis Strait navigators as the "Cape Ice." It brings into Davis Straits great quantities of driftwood and Polar bears. 2. A current down Davis Strait. About Rifkol it is deflected off to the westward, and flows down the western shores of Davis Strait, carrying down great quantities of icebergs, which strand and melt on the banks of Newfoundland, there depositing their loads, others helping to form these banks. Here it meets with the Gulf Stream—the meeting of the cold and warm currents giving rise to the fogs so characteristic of that locality. At the mouth of Davis Strait there is an indraught of the Gulf Stream, which joins the Cape ice on the Greenland coast. It is also to this indraught that the drift mahogany logs, now and then picked up on the Greenland coast, are due. 3. The Gulf Stream, with the exception of the indraught already mentioned, does not enter Davis Strait, but sweeps across the Atlantic, retaining some degree of warmth as far as Novai Zemlai, and landing tropical products on the shores of Iceland and Spitzbergen. It is to this current that is due the freedom of the harbours of Norway and South-Western Iceland from ice.

BOOKS RECEIVED

English.—The Heavens; A. Guillemin, 4th edition, edited by J. N. Lockyer (Bentley).—Travels in the Air: Jas. Glaisher, C. Flammarion, W. de Fonvielle, and G. Tissandier (Bentley).—A Treatise on Magnetism: G. B. Airy (Macmillan).—The Student's Elements of Geology: Sir C. Lyell (Murray).—The Marvels of the Heavens: C. Flammarion, translated by Mrs. Lockyer (Bentley).—Elementary Natural Philosophy: J. Clifton Ward (Trübner).—The Duke of Edinburgh in Ceylon (Provost and Co.).

Foreign.—Jahrbuch der k. k. geologischen Reichsanstalt zu Wien, 1870. (Through Williams and Norgate)—Die Mineralien: J. C. Weber.—Die Fische Deutschlands und der Schweiz: J. C. Weber.

DIARY

THURSDAY, January 12.

Royal, at 8.30.—On Fluoride of Silver, Part II.: G. Gore, F.R.S.—Polarisation of Metallic Surfaces in Aqueous Solutions; Some Experiments on the Discharge of Electricity through Rarefied Med a: C. F. Varley.
Society of Antiquaries, at 8.30.—Election of Fellows.
London Mathematical Society, at 8.—On Systems of Tangents to Plane Cubic and Quartic Curves: J. J. Walker.—On the Order and Singularities of the Parallel of an Algebraical Curve: S. Roberts.

FRIDAY, January 13.

Royal Astronomical Society, at 8.
Quekett Microscopical Society, at 8.

TUESDAY, January 17.

Zoological Society, at 9.—On a Skull of a Narwhal with two tusks, in the Cambridge University Museum: John W. Clark.—Descriptions of some new species of Australian Land Shells: Dr. James C. Cox.—Notes on some points in the Osteology of *Rhea Americana* and *Rhea Darwinii*: Dr. R. O. Cunningham.
Royal Institution, at 3.—Nutrition of Animals: Dr. M. Foster.
Statistical Society, at 7.45.—On the Comparative Taxation on Real Property, Personality, and Income: R. Dudley Baxter, M.A.

THE MEDITERRANEAN ECLIPSE, 1870

CLOUD in Sicily, cloud in Spain, cloud in Africa. Such at first sight might seem to be the only result of all the observations made on the eclipsed sun of 1870; such the reception given by Nature to those who wooed her as she had never been wooed before, who approached her full of the rarest gifts which Science has placed at man's disposal.

But, after all, has the oracle been silent? I think not. Dare we, however, say that the great problem of the Corona, that one among the many still outstanding difficulties which the eclipse was invoked to settle, is settled? This, perhaps, would be saying too much, but still, I think, a step in advance has been made. The oracle has spoken darkly perhaps, but it *has* spoken.

Let me endeavour to put the question as it stood a few weeks ago as briefly as possible.

Beginning the story some few years back we find the corona, a halo of white light round the moon, with a height sometimes represented as equal to the moon's diameter, sometimes more, sometimes less, with a border *à discrétion*, —so much did the drawings vary—regarded as the solar atmosphere.

Some thought the red prominences to be mountains, other observers called them clouds.

The polariscope was brought up with a view of determining whether the corona shone by reflected light or not. The result of this new method of observation was doubtful.

In the Indian eclipse of 1868 M. Janssen, by means of the spectroscope, still another aid, determined that the prominences were masses of hydrogen gas, but there was no final word about the corona. Major Tennant observed that its spectrum was continuous. Later in the same year Dr. Frankland and myself approximately determined the pressure of the prominence gases by means of the new method and laboratory experiments, and at once stated our conviction that the extensive corona which had been depicted and represented by Kirchhoff and others to be the solar atmosphere must be something else. This was our idea. I cannot quote our words, for I am writing in Venice and have no copies of our paper with me.

In the American Eclipse of 1869 the problem was advanced considerably, perhaps even more considerably than we can yet form an idea of, writing as we must still do doubtfully. I do not refer to the drawings, for they varied considerably, but to the observation that the light of the outer corona, like that of the prominences, gave a bright-line spectrum. But as at least some of the observers gave positions doubtfully, "near C" and "near E," I thought that the explanation was still possible which regarded the corona as of terrestrial origin; that is, which assumed it to be an appearance due to the presence of light in our own atmosphere. The problem was one of such difficulty that there seemed a possibility that, by some unexplained cause, some of the solar light might be diffused and beat out of its course, and then, mixing up with the light of the chromosphere, give us a sort of continuous spectrum, with the hydrogen bright lines superposed upon it; in other words, that as the eye perceives a bright, irregular region or glare around the uneclipsed sun, an effect due to our atmosphere, so also the eye might perceive a bright, irregular region or glare round the *uneclipsed chromosphere during eclipses*, due also to our atmosphere.

One word here about the Chromosphere, the name I have given to the bright-line-giving region outside the photosphere. It has long been clear that the spectroscopic method of observing it when the sun is not eclipsed is not totally effective; that is to say, that we only see a percentage of it—perhaps only a relatively small per-centage—but the glowing prominences, that is, those in which there is no evidence of the rapid motion of ejection from the sun, the ejection taking place at all angles from the line of sight, afford evidence that there is probably a layer of cooler hydrogen susceptible of being rendered visible above the ordinary level. Now as these prominences may be 5′ high, it is not unreasonable to suppose that the chromosphere may even extend to that distance, or even a little beyond it.*

Hence it was that in the Instructions to Observers, drawn up by Professor Stokes and myself, and approved by the Organising Committee for this 1870 Eclipse, it is stated that—

"The PRINCIPAL OBJECT to be obtained is to determine whether it is possible to differentiate the outer layers of irregular outline and the streamers (of the corona) from a stratum, say some 5′ or 6′ high, round the sun, which may possibly be the limit of the gaseous envelopes above the photosphere."

The spectroscopic observers, therefore, were enjoined—

a. "To determine the actual height of the chromosphere as seen with an eclipsed sun; that is, when the atmospheric illumination, the effect of which is doubtless only partially got rid of by the Janssen-Lockyer method, is removed. If the method were totally effective, the C line, the line of high temperature, should hardly increase in height; but there can be little doubt that the method is not totally effective, so the increase in height should be carefully noted."

b. "To determine if there exists cooler hydrogen above and around the vividly incandescent layers and prominences."

And the polarisers—

"To examine a detached and selected part of the corona about 6′ from the limb of the sun, and say about 8′ in diameter."

* Here is what I wrote on this point a year ago:—"I next come to the obliterating effect of the illumination of our atmosphere on the spectrum of the chromosphere. This is considerable; in fact, the evidences of it are very much stronger than one could have wished, but hardly more decided than I had anticipated. Professor Winlock's evidence on this point, in a letter to myself, is as follows:—'I examined the principal protuberance before, during, and after totality. I saw three lines (C, near D, and F) before and after totality, and eleven during totality; *eight were instantly extinguished on the first appearance of sunlight*.'" This effect was observed with two flint prisms and 7 inches aperture. Professor Young, with five prisms of 45° and 4 inches aperture, found the same result in the part of the spectrum he was examining at the end of the totality He writes:—'I had just completed the measurements of 2602, when the totality ended. *This line disappeared instantly*, but 2796 [the hydrogen line near G] was nearly a minute in resuming its usual faintness.' These observations I consider among the most important ones made during the eclipse; for they show most unmistakeably that, as I have already reported to the Secretary of the Government-Grant Committee, the new method to be employed under the best conditions must be used with large apertures and large dispersion." (Proc. R. S. 1870, p. 181.)

Having got so far, it may be here stated that of the three means of attack, namely, the spectroscope, the polariscope and telescope, and naked eye observations, the spectroscopic method, under certain circumstances, might have been by far the most doubtful, the polariscope method coming next.

With regard to the spectroscopic observations, if we assume that no light whatever is received by and from our own atmosphere, the observations would be easily translated. A pure continuous spectrum would reveal to us solid or liquid matter in the circumsolar regions; a spectrum continuous or not containing bright lines would give us gases or vapours; the ordinary solar spectrum, with its dark lines, would indicate matter incapable of radiation itself, and therefore cool, reflecting to us ordinary sunlight. It is clear that the problem would be complicated if circumsolar matter both reflected sun light and sent us its own; and still more so if we allow that the coronal light may be partly contributed from reflections and refractions in our own atmosphere. Then we have to consider whether the light thus contributed may possibly be due to the photosphere or to the prominences; and we are landed in a maze of difficulties which need not be discussed here.

The system of sketching introduced for this eclipse is at once so simple and final that the only wonder is it has not been introduced before. The corona must be either solar, atmospheric, or subjective, that is, more or less built up in the observer's eye, this more or less depending *cæteris paribus* upon the brilliancy of the undoubted solar portion. If at all stations, the stations being as wide apart as they have been this time, the drawings are similar, then the corona would be undoubtedly cosmical; if dissimilar, then it would either be terrestrial or subjective: and this point could and would have been settled this time, if the weather had permitted, by arranging the observers *in pairs*, that is, dealing with two observers in each place instead of a single one, and so obtaining the eye-variation.

This being premised, what is the result of the very few observations, comparatively speaking, which have been made? Before I attempt to give any idea of my answer to this question, it is only fair to myself to state that my only sources of information, up to the present time, have been conversations with some of the American members of the Sicilian expedition, a brief telegram from the members of the English party at Agosta, the Rev. S. J. Perry's communication to the *Daily News* of the 2nd instant, and an inspection of some drawings made by the officers of H.M. ships off Aci Reale. At Catania we saw a portion of the corona for 1½ seconds through a cloud, and that was all; and the day after the eclipse, before the more fortunate members of my party returned, it became my duty to proceed to Malta in H.M.S. *Lord Warden* to attend the court-martial on the officers and crew of the beautiful, but unfortunate, *Psyche*, in which we had been wrecked on the 15th ult., and the weather in the Mediterranean has been so bad that it was impossible to leave Malta in time to rejoin the expedition before they left for England. Of detailed information, therefore, I have none.

In the first place, then, I submit that the fact that the corona is a compound phenomena comes out in an unmistakable way. We have first of all a ring some 5′ or 6′ high round the moon, which almost all observers have seen alike; and then we have light beyond which some observers have seen of one shape and some of another, now stellate with many rays, now stellate with few, now absolutely at rest, now revolving rapidly.

This I think to be the key-note of all the observations with which I have become acquainted. I need scarcely say that it is exactly what had been predicted.

First among the fortunate ones who observed the corona with the telescope was Prof. Watson, of Ann Arbor, who took up his station at Carlentini, and appears to have been the best favoured among the Sicilian observers. From his account I gather that there was an almost perfect *shell* around the sun about 5′ high, and that outside this shell were less definite rays. What he was particularly struck with was this, that, as seen in the telescope, the rayed portion was most developed over the prominences, and, as I gathered from him in one case, the rayed portion was absent as if a veil had been removed; so that he, at all events, is strongly impressed with the idea that the shell represented a true solar appendage, and that the rayed structure was due to our own atmosphere.

Next comes Mr. Brett, who, although he was not so fortunate, still was enabled to see and place on record some most interesting features, including the whole outline of the corona and even some of the protuberances. He also, as I am informed, saw the rayed portion of the corona most developed above the protuberances, the outline of the interior portion being visible, though not so strongly marked as in the case of Prof. Watson's drawing, in consequence of less favourable atmospheric conditions. I am thankful to say that the weather at Syracuse enabled Mr. Brothers to obtain some admirable photographs, which I have not yet seen. These are among the most important results of the Expedition.

Next I must mention Prof. Peirce, the head of one of the American parties, who observed two miles north of Catania, at a private casino of the Marchese Sangiuliano. I believe that he also saw the shell, but of this I am not absolutely certain; but he distinctly observed that the outer corona over the prominences was rosy red, although he did not see the prominences himself. A more beautiful proof of the terrestrial nature of this portion of the corona it would be difficult to imagine: for, of course, at the sun, the hydrogen, which thus tinged it, is incapable of colouring anything, as its own light is absorbed by the transcendent brilliancy of the photosphere; while nothing would be more natural than to suppose that the light, which, in its own atmosphere, should strongly tinge anything radially illuminated, should be that of the prominences.

But the strongest proof of the variability of the outer portion and of the constancy of the inner portion is afforded by the observations made on board the small fleet attempting to save the *Pysche* off Aci Reale, where the eclipse was observed in unclouded splendour. Here were the ironclads *Lord Warden*, *Caledonia*, and *Royal Oak*, and the tugs *Weasel* and *Hearty*, besides the Italian gunboat *Plebiscito*, all within a stone's throw of each other. In all the drawings, and many have been received, we have a ring 5′ or thereabouts, while the outer portion is as variable as may be. On the same deck, that namely of the flag-ship, *Lord Warden*, two drawings were made, one by Captain Brandreth, and the other by Dr. Macdonald, F.R.S., in which the variation is so strong that one would feel inclined to acquit the atmosphere of any participation in the matter, and to relegate the whole outer corona to subjectivity alone, did not Mr. Brothers's admirable photographs show both phenomena, as I am told they do. Dr. Macdonald saw eight rays arranged with perfect symmetry; Captain Brandreth saw only two elliptical hoops crossing each other at right angles.

Captain Cochran, of the *Caledonia*, besides the ring, saw a complicated stellate figure, the rays of nearly equal length, while Mr. Dexter, at sea between Catania and Syracuse, saw, besides the ring, *only one ray* of inordinate length.

So much for the drawings. I think that if the records of former eclipses be now examined, especially Mr. Carrington's drawing of the eclipse of 1851, and compared with the others taken at the same time, additional evidence will be gathered in favour of the compound nature of the corona, which, on the evidence now before me, I consider the great teaching of the present eclipse. Our experience in Sicily seems to be similar to that of the Spanish observers, for Mr. Perry writes that "some observed two curved rays," while the rapid degradation of light occurred at one-fifth of a solar diameter, but, so far as I know, no one in Sicily was favoured with a view of the dark intervals which were observed in Spain.

There is a strange and most interesting discordance between some of the spectroscopic observations made in Sicily and Spain. At Agosta, where the totality was well visible for ten seconds, Mr. Burton detected a green line near E, with a tangential slit (distance from moon not stated). This line, which was also seen by the Italian observers, is doubtless the one recorded last year by the American astronomers, but in Spain Mr. Perry states that bright lines at C near D, *b* (or E) and F were observed 8′ away from the sun. At Syracuse Prof. Harkness, whose telescope was moved into the various positions by Captain Tupman, R.M.A., found the green line in all parts of the corona, so far as about 10′ from the sun, and at one point thought he detected two green lines, less refrangible than it; but at several places he saw a complete hydrogen spectrum (including C), which he attributed to prominences, until he was informed by Captain Tupman that there was no prominence near the slit. More proofs of the terrestrial nature of this portion of the corona, I think, taken in connection with the fact that *the dark moon gave identically the same spectrum*. It would appear that there was so much atmospheric reflection in Spain, and here and there at Syracuse, that the true coronal spectrum with its line near E, the existence of which we must now accept as established beyond all question, was partially masked by the prominence spectrum with its usual well-known lines. There is one passage in Mr. Perry's interesting letter in which, if there be a misprint, as I suspect there is, an observation of great importance is recorded. It runs, "Mr. Abbay, observing at Xeres with a spectroscope of 2 prisms of 45° belonging to Professor Young, saw the bright lines C, D, F; and afterwards F and a line rather more bright than F on the less refrangible side of B, C not noticed then." Now, if *b* (not B) was intended here we have sub incandescent hydrogen mixed with the green-line-giving-substance, which may probablybe a new element with a vapour density less than hydrogen.

So that roughly we might regard the chromosphere to be built up of the following layers, which are in the orders of vapour density in the case of known elements:—

X′ (new element)	. . . . .	Green coronal line
Hydrogen	Sub-incandescent	F
	Incandescent	C, F, near G, h
X (new element)	. . . . .	Near D
Magnesium	. . . . . .	*b* and lines in blue and violet
Sodium.	. . . .	D
Barium	. . . .	Several lines
Iron, &c.	. . . .	Several lines, including E

The foregoing table excludes naturally the substance or substances which give bright lines in the solar spectrum, which are at times visible in the spectrum of the chromosphere. I have ventured to suggest that the substance which gives the line in the green is a new element, because invariably I have found that in solar storms the chromospheric layers are thrown up in the order of vapour density, and because all the heavier vapours are at or below the level of the photosphere itself.

With regard to the question of polarisation, the parties in Sicily obtained evidence that the corona was radially polarised, though Professors Harkness and Eastman obtained a result which they explain differently. Mr. Ranyard, at Villamonda, and Mr. Peirce, jun., north of Catania, obtained identical results in favour of strong polarisation. Hence the solar corona, accepting these observations, not only radiates, but reflects solar light to us. A careful consideration of this fact, taken in connection with the possible addition of a, so to speak, terrestrial corona to its light, may enable us to account for some of the observations, both polariscopic and spectroscopic, which do not at first appear to harmonise with those to which I have referred, notably those which give a pure continuous spectrum to the corona, and which state that its light is only slightly polarised.

From what has preceded, then, we seem justified in suggesting as working hypotheses the following, which, however, more accurate information may alter, and which I offer as suggestions only, *bien entendu*.

1. The Solar Chromosphere extends some 5′ or 6′ from the sun (Watson and others), its last layers consisting of cool hydrogen (Mr. Abbay), and possibly a new element with a green line in its spectrum (Young, Burton, and others); which line, if it be identical with the auroral line as stated by Gould, may possibly be present in the higher regions of our own atmosphere.

2. Outside this stratum the rays, &c., are for the most part due partly to our own atmosphere, partly to our eyes, for their shape varies; they are seen by some at rest, by others in motion, and their spectrum is the same as that of the dark moon (Maclear).

3. The white light of the chromosphere above the prominences, as seen in an eclipse, is due to its strong reflection of solar light, as shown by the polariscopic observations (Ranyard, Peirce, jun., Ladd).

4. The rosy tinge of the corona proper, that is of the region more than 5′ or 6′ from the sun, is due to our atmosphere containing light which comes from both the higher and lower strata of the chromosphere (Peirce, sen., Maclear, Abbay).

Venice, Jan. 9 J. NORMAN LOCKYER

A HEARTH OF THE POLISHED STONE AGE

Note sur un Foyer de l'Age de la Pierre polie découvert au Camp de Chassey en Septembre, 1869. Par Ernest Perrault. 1870. 4to. Pp. 32, and 8 plates. (Chalon sur Saône, L. Landa. London: Williams and Norgate.)

ON the summit of a steep hill between the valley of the Bas Roches and that of the Dheune, overlooking the immense plain of the Saône and commanding a view of the Jura, the Alps, and the mountains of the Maconnais and the Morvan, and surrounded by numerous other camps, is the camp of Chassey, which occupies an area of about 800 yards in length by a breadth varying from about 100 to 200 yards. So commanding and important a spot was not only taken possession of by the Romans for a *castellum* and by the Gauls for an *oppidum*, but was also occupied in prehistoric times. Several collections of antiquities belonging to different periods have been formed upon the spot, but it was reserved for M. Perrault to make the interesting discovery which he has recorded in so simple yet so complete a manner in the pages now before us. A terrace, sheltered by rocks from the north and east winds and facing the morning sun, seemed to him well adapted for early habitations, while a depression in the ground in front proved, on examination, to contain the remains of a large hearth, or it might be termed kitchen, and here he instituted excavations.

Beneath a few inches of soil he found a bed rather more than two feet in thickness, made up of ashes, bones, and pottery, and containing numerous instruments of various kinds. The whole reposed on a platform of rough slabs of stone, blackened like the soil beneath them by the action of fire. Not a trace of metal was discovered, and in describing the objects found, M. Perrault divides them into (1) instruments of stone, (2) those of bone, and (3) pottery.

Exclusive of fragments some 150 stone instruments were found, consisting for the most part of hatchets, arrow-heads, flakes, borers, scrapers, hammers, mealing stones, and polishing stones. No less than eight perfect stone hatchets were found, as well as fourteen broken, and of those that were uninjured two were still mounted in stag's-horn sockets, similar to those with which the discoveries in the Swiss Lake dwellings have made us so well acquainted.

Only two are of flint, and one of fibrolite, the others being of chloromelanite, serpentine basalt, and diorite. They seem to have been formed from pebbles brought down by the Saône, and it is interesting to observe that the same process of manufacture was in use in this part of Burgundy as in Switzerland, the splitting of the pebbles into the required form having been partly effected by sawing. That some of the spare hours of those who frequented the hearth were employed in preparing their hatchets is proved by the large number of grinding or polishing stones, of which, counting fragments, upwards of sixty were present. M. Perrault regards one of the smallest of the cutting instruments, a little triangular celt, as a religious emblem, but it seems more probable that it was used as a hand-tool, like a chisel, of one of which the sharpened end was also found.

The arrow-heads of flint, twenty-three in number, present a variety of forms, leaf-shaped, triangular, lozenge-shaped, and tanged, the latter both with and without barbs. Their general aspect is such as might have been expected from the locality, most of the forms occurring also in Switzerland. There are, however, one or two shaped like small hatchets, with a broad sharp base, formed by the original edge of the flake from which they were made, and rounded or truncated at the other end. It is stated that this sharp edge was intended for insertion in the wood, but more probably it was the other end that was thus secured, and the arrows were, so to speak, chisel-pointed, like the flint-tipped arrows which survived in use, probably for fowling purposes, after metals became known to the ancient Egyptians. Similar arrow-heads, if such they be, have been found in considerable numbers in Sweden, and a few in Denmark, as well as in some other parts of France. It seems by no means impossible that some of the sharp-based instruments from the Yorkshire Wolds may have served a similar purpose.

The mealing stones consist of a large block, usually of hard sandstone or porphyry, and a smaller stone as muller, and are of the same character as those still in use in Central Africa. They must have been gradually eaten together with the flour they produced, and no doubt tended to promote that wearing away of the crown of the teeth so common in ancient times. None of the grain has been found, but probably most of the cereals known to the old Swiss Lake dwellers were also known at Chassey.

The objects in bone and horn are almost identical with those from the earlier Swiss Lake dwellings, and consist of the sockets already mentioned, awls, chisels, &c. The pottery, which is extremely fragmentary, is much of the same character as the Swiss. It has been ornamented both by punctured dots and by a sort of pillar moulding as well as by incised lines. In one instance there seems to have been an attempt to represent the outline of a boar by lines scratched in the clay when still moist. In another, the ornament consists of bands of triangles alternately cross-hatched and plain, a style more in accordance with the bronze age than with that of stone. Most of the pottery seems to have been adapted for suspension. The number of small ears or handles found exceeded 200. A few spindle-whorls and beads were also found, but the most curious objects are the spoons, exactly similar in form to those of wood in common use in our kitchens at the present day, but formed of clay. It is true that several wooden ladles and at least one earthenware spoon were found in the settlement of Robenhausen, but one can hardly repress a feeling of surprise at finding the spoon so fully and completely developed among a people apparently unacquainted with the use of metal, though it is true that they appear to have had the materials for porridge at their command.

In concluding this short notice of a valuable contribution to prehistoric archæology, a regret must be expressed that the animal remains discovered in the refuse heap have not, apparently, as yet been submitted to proper scientific examination, so as to determine the species, and which of them were domesticated, though some human remains from neighbouring tumuli and interments are reported on by Dr. Pruner-Bey. The animals whose bones occurred are described as ox (possibly domesticated), pig, stag, sheep, goat, and horse, which is rare. The bones are not always broken, and the vertebræ occasionally occurred in juxtaposition, as if meat at times had been extremely abundant. There is no mention of any remains or traces of dogs, and this condition of the bones seems to afford an argument in favour of their absence, which, if established, would be a remarkable fact. Some teeth of reindeer are mentioned as having been found on the plateau, and it would be of great interest to ascertain their relation to the other remains. Let us trust that ere long there may again be a season in France when a though may fairly be bestowed on other camps and other earthworks than those on which attention is now so unfortunately concentrated.

J. E.

SPONTANEOUS GENERATION

I HAVE repeatedly subjected various solutions for Dr. Bastian to a temperature of 150° to 156° C. in sealed vacuous tubes, in order that he might afterwards submit them to a microscopical search for living organisms. The result of this search led him to conclude that living organisms had been generated from non-organised matter, whilst Professor Huxley, who examined the contents of one of the tubes, considered that no such conclusion could be drawn from his own observations. I therefore determined to repeat these experiments, operating in exactly the same manner as before in the preparation of the solutions, the sealing them up in vacuous tubes, and exposing them to a high temperature, but taking additional and much more stringent precautions against the subsequent admission of atmospheric germs into the tubes.

For this purpose four tubes of hard Bohemian glass were prepared, and about half-filled with a liquid consisting of

Carbonate of Ammonia . . .	15 grains.
Phosphate of Soda	5 grains.
Distilled Water	1 oz.

No care was taken to exclude living germs from these ingredients, reliance being placed, for the destruction of their vitality, upon the high temperature to which they were afterwards subjected.

These tubes were carefully exhausted by means of the Sprengel pump, and hermetically sealed; they were then, on July 18, 1870, exposed for four hours to a temperature varying from 155° to 160° C. in a Papin's digester. After being allowed to cool, the digester was opened, and the tubes immediately plunged, two of them into colourless concentrated oil of vitriol, and the remaining two into a nearly colourless saturated solution of carbolic acid in water. These precautions were taken in order to avoid the possible admission of atmospheric germs through invisible cracks in the glass; such cracks, entirely invisible to the eye, are known sometimes to exist, and to be in some cases so excessively minute as to require several days for the admission of enough air to perceptibly impair a torricellian vacuum within. By keeping the tubes entirely immersed in liquids which are immediately fatal to vitality, I hoped to meet any objections that might be raised, in the event of living organisms being subsequently found in the tubes, that the germs of such organisms had gained access to the enclosed liquids through invisible fissures in the glass. On examining them when they came out of the digester, it was evident that the interior walls of the glass tubes had been corroded by the enclosed liquid, and as the tubes had stood upright in the digester, it was easy to see, by the sharp limits of the erosion, the extent to which the liquid had expanded under the influence of the high temperature to which it had been exposed.

The cylinders containing the immersed tubes were now maintained at a temperature from 60° to 75° F., and were exposed to bright diffused daylight, and sometimes to sunlight, for a period of more than five months.

The liquid in all the tubes became more or less turbid, and in some cases a small quantity of a light flocculent precipitate subsided to the bottom. On the 24th of December last two of the tubes, which exhibited the greatest turbidity, were selected for examination (one of them had been immersed in concentrated sulphuric acid, the other in the solution of carbolic acid). The vacuum was unimpaired, and the liquid in the interior formed a good water hammer. These tubes were opened in the presence of Prof. Huxley and Mr. Busk, and we submitted their contents to a searching microscopical examination with powers varying from $\frac{1}{8}$th to $\frac{1}{16}$th. Especially was the flocculent sediment in the tubes subjected to careful inspection. So far as the optical appearances presented by the sediment go, they may be appropriately described in the terms which Dr. Bastian applied to the matter found by him in a solution of like composition and simiarly treated (see NATURE, July 7, 1870, p. 200). "A number of little figure-of-eight particles, each of which was $\frac{1}{20000}$" in diameter, were seen in active movement, even in situations where they could not have been influenced by currents. The portions of the pellicle were made up of large, irregular, and highly refractive protein-looking particles imbedded in a transparent jelly-like material. The particles were most varied in size and shape, being often variously branched and knobbed. There were also seen several very delicate, perfectly hyaline vesicles, about $\frac{1}{30000}$" in diameter, these being altogether free from solid contents." But the movement of the particles which we observed was obviously mere Brownian motion; and many of the particles were evidently minute splinters of glass. There was not the slightest evidence of life in any of the particles. The water on the slide containing these solid matters was evaporated off, and they were treated with hot concentrated sulphuric acid, the temperature of the slide being raised to about 100° C. There was no blackening, and the rounded and dendritic bodies remained as entirely unaltered as the glass splinters. Indeed, some of the larger spheroidal bodies were evidently rounded particles of glass which had become detached from the inner walls of the tube by the corrosive action of the enclosed liquid at the high temperature to which it had been exposed in the digester.

London, January 16 E. FRANKLAND

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

The Continuity of the Chalk

SIR CHARLES LYELL devotes a paragraph of his valuable "Students' Elements of Geology," just published, to the consideration of what he regards as a "popular error as to the geological continuity of the Cretaceous period." I feel the utmost diffidence in venturing to controvert any opinion of an authority so unrivalled in such questions, but as I believe the first definite suggestion of this view occurs in the report of the *Lightning* Expedition of 1868 by my friend and colleague, Dr. Carpenter, where it is specially associated with my name, I feel bound to defend so far as I can, or at all events to explain, an opinion which I then held on perhaps somewhat slender grounds, but which further investigation and reflection have since ripened into a firm belief. Sir Charles Lyell says (p. 263) that "certain points of resemblance which the deep-sea investigations have placed in a strong light, have been supposed by some naturalists to warrant a conclusion expressed in these words: 'We are still living in the Cretaceous epoch;' a doctrine which has led to much popular delusion as to the bearing of the new facts on geological reasoning and classification." I do not say that the phrase "we are still living in the Cretaceous epoch" is defensible in a strictly scientific sense, chiefly because the terms "geological epoch" and "geological period" are thoroughly indefinite. We speak indifferently of the "Silurian period" and of the "Glacial period," without consideration of their totally unequal value, and of the "Tertiary period," and of the "Miocene period," although the one includes the other. It is ntended rather, I believe, in a popular sense, to meet what seems to be the general popular impression, that a geological period has, in the region where it has been studied and defined, something in the shape of a beginning and an end, that it is bounded by periods of change,—elevation, denudation, or some other evidences of the lapse of unrecorded time; and that it would be inadmissible to speak of two portions of the same continuous deposit, however distant the times of their deposition might be, and however distinct their imbedded faunæ, as belonging to two geological periods.

It was certainly under this idea that in an address to a popular audience in April 1869, I stated my belief that it is not only chalk which is being formed at present in the bed of the Atlantic, "but *the* chalk, the chalk of the Cretaceous period." Sir Charles Lyell says, in summing up his objections at the end of the paragraph, "the reader will at once perceive that the present Atlantic, Pacific, and Indian Oceans are geographical terms, which must be wholly without meaning when applied to the Eocene, and still more to the Cretaceous period; so that to talk of the chalk having been uninterruptedly forming in the Atlantic from the Cretaceous period to our own, is as inadmissible in a geographical as in a geological sense." I confess I do not understand the geographical difficulty; the "Atlantic Ocean" is doubtless a geographical term, but the depression under discussion occupies the area at present expressed by that term, and to use it seems to be the simplest way of indicating its position. That it is highly probable that the chalk has been so uninterruptedly forming over some parts of that area, is, however, exactly what I wish to show. I will therefore set aside the question of expression, and address myself simply to the consideration of the fact. And first with reference to the physical aspects of the case.

All the principal axes of elevation in the north of Europe and in North America have a date long anterior to the deposition of the Tertiary and even of the newer Secondary beds; and these strata were, consequently, all deposited with a certain relation in position to certain main features of contour, which are maintained to the present day. Many oscillations have, undoubtedly, taken place since, and every spot on the European plateau has probably many times alternated between sea and land, but it is difficult to show that these oscillations have occurred in the latitude of Britain to a greater extent than 1,500 feet up and down; a subsidence to that extent would, however, be sufficient to produce over most of the northern land a sea 100 fathoms deep, the average depth of the German Ocean.

From a glance at a geological map of Europe and North America, it would seem that the sum of these elevations and subsidences has produced a gradual elevation of the edges, and a general contraction, of a basin the long axis of which coincides roughly with the axis of the Atlantic. The Jurassic beds crop out along the outer edge of this basin, the Cretaceous beds form a middle band, while the Tertiaries occupy the troughs and valleys. All of these, however, maintain a certain parallelism, determined by the contour of the older mountain ridges, to one another and to the shores of the present sea.

From the parallel of 55° N. lat., at all events to the equator, we have on either side of the Atlantic a depression 600 to 700 miles in width, averaging 15,000 feet in depth.

These two valleys are separated by the modern volcanic plateau of the Azores. I cannot think it at all probable that any general oscillations have taken place in the northern hemisphere since the commencement of the Tertiary period sufficient to form that immense abyss, or, if formed, to convert it into dry land; but on this point I am able to quote the highest authority:—"If at any former period the climate of the globe was much warmer or colder than it is now, it would have a tendency to retain that higher or lower temperature for a succession of geological epochs. . . . The slowness of climatal change here alluded to, would arise from the great depth of the sea as compared to the height of the land, and the consequent lapse of time required to alter the position of continents and great oceanic basins. . . . The mean height of the land is only 1,000 feet, the depth of the sea 15,000 feet. The effect, therefore, of vertical movements equally 1,000 feet in both directions, upward and downward, is to cause a vast transposition of land and sea in those areas which are now continental, and adjoining to which there is much sea not exceeding 1,000 feet in depth. But movements of equal amount would have no tendency to produce a sensible alteration in the Atlantic or Pacific Oceans, or to cause the oceanic and continental areas to change places. Depressions of 1,000 feet would submerge large areas of the existing land, but fifteen times as much movement would be required to convert such land into an ocean of average depth, or to cause an ocean three miles deep to replace any one of the existing continents." (Lyell, "Principles of Geology," 1867, pp. 265-6.) The wide extent of Tertiaries in Europe and the north of Africa sufficiently proves that much land has been gained in Tertiary and post-Tertiary times, and the great mountain masses of Southern Europe give evidence of great local disturbance. But although the Alps and the Pyrenees are of sufficient magnitude to make a deep impression upon th senses of men, taking them together, their materials would, it spread out, only cover the surface of the North Atlantic to the depth of about six feet, and it would take at least 2,500 times as much to fill up its bed. It would seem by no means improbable that while the edges of what we may call the great Atlantic depression have been gradually raised, the central portions may have acquired an equivalent slight increase in depth; but it is most unlikely that while the main features of the contour of the northern hemisphere remained the same, an area of so vast extent should have been depressed by more than the height of Mont Blanc. On these physical grounds alone I should be inclined to believe that a considerable portion of this area has been continuously under water, and that consequently a deposit has been forming uninterruptedly from the period of the chalk to our own.

I would now refer to the palæontological bearings of the question. Sir Charles Lyell says (p. 263), "The reader should be reminded that in geology we have been in the habit of founding our great chronological divisions, not on foraminifera and sponges, nor even on echinoderms and corals, but on the remains of the most highly organised beings available to us, such as mollusca. . . . In dealing with the mollusca, it is those of the highest or most specialised organisation which afford us the best characters in proportion as their vertical range is the most limited. Thus the cephalopoda are the most valuable, as having a more restricted range in time than the gasteropoda, and these again are more characteristic of the particular stratigraphical sub-divisions than are the lamellibranchiate bivalves, while these last again are more serviceable in classification than the brachiopoda, a still lower class of shell-fish, which are the most enduring of all." With great deference to Sir Charles Lyell, I cannot regard the most highly specialised animal groups as those most fitted to gauge the limits of great chronological divisions, though I admit their infinite value in determining the minor sub-divisions.

The culmination of such animal groups, such as we find in the marvellous abundance and variety of both orders of cephalopods at the end of the Jurassic and the commencement of the Cretaceous period, undoubtedly brings into high relief, and admirably illustrates to the student, the broad distinctive characters of the Mesozoic fauna; but speaking very generally, the more highly a mollusc is specialised, the shallower is the water which it inhabits. The cephalopods are chiefly pelagic and surface things, and their remains are consequently found in deposits from all depths. The gasteropods, with comparatively few exceptions, range from the shore to 1 to 200 fathoms, and lamellibranchs become scarce at a slightly greater depth; while some orders of crustacea, brachiopods, echinoderms, sponges and foraminifera, descend in scarcely diminished numbers to a depth of 10,000 feet. In fact, the bathymetrical range of the various groups in modern seas corresponds remarkably with their vertical range in ancient strata.

A change in the distribution of sea and land involving a mere change in the course of an ocean current, might modify the conditions of an area for all cephalopods, pteropods, heteropods, and other surface living animals of high type, even to their extinction. By oscillations of 500 feet up and down, the great mass of gasteropods and all reef-building corals, would be forced to emigrate, become modified, or destroyed, and another hundred fathoms would exterminate the greater number of bivalves; while elevations and depressions to ten times that amount might only slightly affect the region of brachiopods, echinoderms, and sponges.

In the late deep-sea dredgings by M. de Pourtales, off the American coast, and by H.M.S. *Lightning* and *Porcupine*, and

Dr. Marshall Hall's yacht *Norna* off the west coast of Europe, no animal forms have been discovered, so far as I am aware, identical with chalk fossils. Additional evidence has, however, been procured that over a large part of the bottom of the Atlantic a deposit is being formed mainly of disintegrated globigerinæ and other foraminifera and coccoliths, which appears to be undistinguishable from the ancient chalk.

Not fewer than twenty genera of vitreous sponges have been dredged belonging to two groups, the Hexactinellidæ and the Lithistidæ of Oscar Schmidt, both of which groups are highly characteristic of the chalk and greensand. These sponges are in vast numbers, like the ventriculites and their allies in older Cretaceous beds; and they, with other silicious organisms equally abundant in the modern chalk area, seem to be capable of supplying that amount of silica in a fine state of division which might explain the production of chalk flints. A large series of echinoderms were found, recalling to a remarkable degree, from the profusion of Cidarids and of star-fishes of such genera as Archaster, Astrogonium, and Stellaster, the general facies of the chalk echinoderm fauna; and besides this general resemblence, members of several families have been recovered which were supposed to be extinct. *Salenocidaris varispina* A. Ag., dredged by De Pourtales in the Strait of Florida, is a living Salenia; *Echinolampas caratomoides* A. Ag. perpetuates some of the most marked characters of the Galeritidæ. *Pourtalesia*, a genus first found by Count Pourtales and afterwards in the *Porcupine* expedition, is a true Dysaster. *Porocidaris purpuratus*, a fine species dredged off the Butt of the Lews, represents a genus hitherto known only by some isolated plates and radioles. Two very remarkable generic forms, dredged from the *Porcupine* off the coasts of Scotland and Portugal, only known from some fragments in the English white chalk, found a new family near the Diademidæ. Some new ophiurids approach their fossil ancestors; and off the coast of Portugal the dredge brought up at one rich haul twenty or thirty examples of a fine *Pentacrinus*; while over the whole area *Rhizocrinus loffotensis*, a degenerate little Bourgueticrinus, seemingly one of the last of the pear-encrinites, is abundant.

I am not in a position to say much about those groups which I have not personally examined, except that Mr. Gwyn Jeffreys and Prof. Martin Duncan report that among the mollusca and corals many species occur which have been hitherto known only as fossils, principally, as might have been expected, in comparatively shallow water forms in the Tertiaries.

I do not see that there is any object in attempting to explain this singular resemblance between these deep-sea deposits in the Atlantic and the old chalk in composition and structure and in embedded fauna on any other assumption than that of a continuity of conditions over some part at all events of the area. During the lapse of time, while the fauna of shallower water has again and again undergone almost total change by changes in the distribution of temperature and in the distribution of sea and land, the fauna of the deep water has been also affected. To a depth of 5,000 feet it is at present heated over a large portion of the North Atlantic many degrees above its normal temperature. Accepting, as I believe we are now bound to do, some form of the doctrine of the gradual alteration of species through natural causes, one is quite prepared to expect a total absence of the identical forms found in the old chalk. The utmost which might be anticipated is such a resemblance between the two faunæ as might justify the opinion that the later fauna bears to the earlier the relation of descent with extreme modification. Sir Charles Lyell asks if we have dredged belemnites, ammonites, baculites, hamites, turrilites, &c.; that question is, I think, best answered by the record of the old Cretaceous beds themselves, which are scarcely more remarkable for the presence of these singular and beautiful forms than for their rapid extinction. According to the view which I have felt myself compelled to adopt, the various groups of fossils characterising the Tertiary beds of Europe and North America represent the constantly altering fauna of the shallower portions of an ocean whose depths are still occupied by a deposit which has been accumulating continuously from the period of the pre-Tertiary chalk, and which perpetuates with much modification the pre-Tertiary chalk fauna. I do not see how this view militates in the least against the "reasoning and classification" of that geology which we have learned from Sir Charles Lyell. Our dredgings only show that these abysses of the ocean which Sir Charles Lyell admits in the passage quoted above to have outlasted on account of their depth a succession of geological epochs, are inhabited by a special deep-sea fauna possibly as persistent in its general features as are the abysses themselves.

WYVILLE THOMSON

Ocean Currents

ATTENTION has been much drawn of late to the subject of Ocean Currents and their causes, and it has occurred to me that there is a directing if not an originating cause of these streams, which has, so far as I am aware, been overlooked by physicists. It is known* that at some parts of the earth's surface there exists an atmospheric pressure capable of sustaining a column of mercury in the barometer of upwards of 30 inches in height; at the same time there are certain areas over which this pressure is only such as to raise the barometric column to a little over 29 inches. Now if we compare the difference of absolute weight sustained by two such areas, we shall see that in the space over which the higher atmospheric pressure exists, there is an excess of weight of air, amounting in round numbers to 1,000,000 of tons on each square mile. Applying this fact to the region of the ocean in which the surface currents are best known, the North Atlantic, we find from the isobaric chart that there is throughout the year over a large portion of the eastern side of this sea, next the coast of North Africa, a pressure (to use the convenient mode of expressing it) of upwards of 30·2 inches. To westward of this space, towards the Gulf of Mexico and the coast of the United States, the average pressure decreases; between Newfoundland and the British Isles the pressure is still diminished, till in the wide channel between Iceland, Norway, and Spitzbergen, we arrive at a yearly pressure of less than 29·6 inches. It is reasonable to believe that the waters which lie under the high pressure area have a tendency to escape from under the excessive weight, towards the space over which the pressure is less. But the high pressure area next the African coast is precisely that upon which the north-east trade winds descend, and the waters, aided in their choice of an exit, will naturally flow off to south-westward before the wind. Their continuance in this direction is barred, however; for across the whole of the southward passage between Africa and South America, there exists another belt of high pressure, out of which the south-easterly trade winds blow. The only course left for the escaping waters (allowing for the moment that the excess of pressure *is* a cause of their movement) is to westward, where the pressure is lessened, towards the Gulf of Mexico, and the east coast of America, and thence towards the low pressure space between Iceland and Norway. But this is exactly the course that the Gulf Stream, or rather the North Atlantic warm stream of which the Gulf Stream is the most prominent feature, is seen to take. Are we not then warranted in concluding that the difference of atmospheric pressure has some power both in originating and in directing the course of this ocean current?

In suggesting the unequal distribution of atmospheric pressure as a supplementary cause to difference of temperature and of density, to evaporation, rain, and winds, and to whatever further agents there may be in the production of ocean currents, I would venture to express a hope that some one in authority, by carefully comparing and valuing the power of each one of these motive forces, and their application to the known streams, will give to the world a system of the causes of ocean currents which will be vastly more relevant to the phenomena these streams are known to present, than any one of the theories which have as yet been put forth.

When we know that Sir John Herschel gives to the winds the entire right of setting the ocean streams in motion; that Captain Maury holds the universal circulation of the sea to be caused by nothing else than the differences in its specific gravity, and that Dr. Carpenter (or rather Professor Buff) would bring about a general interchange of polar and equatorial water by the aid of sunshine and frost alone; is it not time to ask which of these three causes we should accept as the true one, or if all three are partially concerned, what part is to be taken from each to let the others have their fair share in the work?

KEITH JOHNSTON, Jun.

* I would refer those who desire to look more particularly into this matter to the monthly isobaric charts prepared by Mr. Buchan, to illustrate his admirable paper on the mean pressure of the atmosphere. Trans. Royal Soc. Edin., vol. xxv.

The Measurement of Mass

I AM happy to meet with an opponent who comes so directly to the point as my Reviewer, W. M. W.

The gist of his argument lies in his assertion, that "if a true pound, as determined at London, were carried to the North Pole, it would weigh more than a pound."

Now, since the determination of a pound is actually effected by making it a copy of a standard so that they shall counterpoise each other *in vacuo*, it is strictly independent of locality.

The standards actually employed for this purpose, for example, the authorised copies of the principal standard pound which have been sent to various countries, have been made as nearly identical in mass as skilled workmen could make them, and have been sent at random to different latitudes.

Similar remarks apply to the weights in a chemist's box. Surely it is not seriously proposed that the chemist should file them down to accommodate them to the increase of gravity, when he takes them from London to Edinburgh.

Where should we find ourselves, if the makers of chemists' weights endeavoured to make them of different masses, according to the places where they were to be used?

Fortunately, this has never been attempted; and since all parts of the world are in possession of practically identical standards of mass, under the name of standard pound or standard kilogramme, and tolerably accurate copies of these and their fractional parts are in everybody's hands, why not acknowledge them as standards of mass, which they are in point of fact, although, according to the theory which I am combating, they ought not to be?

Those who hold that theory must choose between two evils:—they must either make the pound a unit of force, in which case they must file or load their weights as they go from place to place (this seems to be the alternative which W M. W. chooses); or they must accept the gravitating forces of equal pieces of metal as nominal units of force at the different localities where these pieces of metal may happen to be, although these forces are really not equal. This latter alternative, which gives a variable unit of force, has been commonly adopted till recently, and a variable unit of mass has been conjured up to suit it.

If our spring-balances were as accurate as our standard weights, W. M. W.'s idea would be practicable. The equality of two forces at different places could then be very directly tested; but, in fact, the most accurate means we possess of making such a comparison consists in a double process, a weighing with the ordinary balance, combined with a difficult and less accurate pendulum-comparison. Inasmuch then as ease and accuracy of comparison is the first essential of a scientific standard, I submit that the world is right in employing standard pounds of equal mass and not standard pounds of equal gravitating force.

Much confusion arises from using the word *weight* in a connection which leaves it doubtful whether *mass* or *gravitating force* is meant. I trust you will keep your columns open for the further discussion of this question, as it much needs ventilation.

Belfast, January 11 J. D. EVERETT

The Tails of Comets, the Solar Corona, and the Aurora considered as Electric Phenomena

IN reference to a letter from Mr. Bedford, Ph.D., published in your last number, allow me to state—

1. That I had never seen or heard of Dr. Bedford's theories.
2. That, judging from the extract given in his letter, Dr. Bedford has not published anything analogous to the electrical hypothesis which I have put forward. In his letter he has misquoted and made omissions to the extent of one-half the heading, in order, I suppose, to avoid the very mention of the word electricity, which, on the other hand, is the very substance of my postulate. OSBORNE REYNOLDS

Owens College, Jan. 17

Apparent Size of the Moon

FROM almost any place in the balcony of St. James's Hall, at an evening performance, one may find in the coronets of gas-jets, forming one or more of the arches across the roof, corroboration of what I wrote in NATURE of May 12, 1870 (vol. ii. p. 27). The nearest or first coronet, and the two next, observe a gradation of increase in apparent magnitude, as they should do. But the rest, which (unlike those three) descend towards the horizon, and should, nevertheless, observe a gradation of increase, are apparently all of a size. I call attention to this "unconsidered trifle" as having the full force of a very elaborate experiment. C. M. INGLEBY

Ilford, Jan. 7.

Atmospheric Currents

THE following is part of a letter signed "G." in NATURE of 6th October, 1870:—

"It is very important to obtain correct and copious data regarding the atmospheric currents between say 5,000 feet and five miles above the level of the sea, and especially at various points on and near the equator, and at about 30° to 32° North and South latitudes. Within these limits the rain-bearing currents of the atmosphere move. If self-registering meteorological instruments were placed permanently upon several of the leading mountain ranges of the world, and their records copied at stated intervals, we should obtain valuable data for determining the direction, velocity, and magnitude of the controlling atmospheric currents of the globe."

This suggestion is most valuable, but it would involve a source of error that would be difficult to allow for. Most mountain ranges occupy so extensive an area that they have their own local climates, and indications on such ranges would consequently not give accurate information about the currents where they are not modified by such influences. The most valuable information will be obtained from the most isolated mountains. The most isolated mountains of sufficient height, within sufficiently easy reach of us, are Etna and Teneriffe. Etna is in the variables, and Teneriffe in the trade-winds.

I do not, however, agree with the following suggestion, that more valuable observations still might be obtained by means of captive balloons. Balloons cannot be used in stormy weather, and they are also subject to the great disadvantage, that they tell nothing about barometric fluctuations: because the height of a balloon above the earth can be known only from the barometer, and consequently there is no way of ascertaining the indications of the barometer at a known height. It is not at all certain that the barometric curves at the summit and at the base of Etna or Teneriffe would present any close correspondence. Sets of barometrical and other meteorological observations taken for sufficiently long periods at the summit and at the base of such mountains would be probably the most valuable of all data for meteorological science in its present state.

JOSEPH JOHN MURPHY

Old Forge, Dunmurry, Co. Antrim, Jan. 14

THE AMERICAN ECLIPSE EXPEDITION

THAT portion of the American Eclipse Expedition which was stationed at Xeres was favoured by weather which enabled the observers to examine the Corona during the whole period of totality, and with some results of interest; an informal account of a part of which the kindness of Professor Winlock enables me to lay before your readers.

The party was in charge of Professor J. Winlock, and stationed in an olive grove about a mile from the city, the property of Mr. Davies, of Xeres, to whom all the members of the expedition are indebted for continual aid and kindness. The observations for the determination of longitude, latitude, and times of contact were conducted by Assistant G. W. Dean, of the Coast Survey, aided by Captain Ernst, of the U.S. Engineers, and by Mr. Gannett, of the Harvard College Observatory.

Their labours were facilitated by the courtesy of the Director of the neighbouring Observatory of San Fernando, with which telegraph connection was established, and the results attained will be found in full in their official report.

Besides the instruments of precision, the party was provided with four equatorial telescopes of from six to eight inches aperture, driven by clockwork, and many smaller ones. One of the largest telescopes carried an objective specially corrected for actinic rays, with which, and a companion instrument, photographs were taken during the totality and previous stages by Mr. Willard and his assistant.

In addition, a photographic telescope of upwards of thirty feet focus, placed horizontally, and receiving the solar rays from a heliostat, was used, in charge of Mr. Gannett.

The accessories of the instruments were such as the previous experience of the observers (nearly all of whom had witnessed the eclipse of August 1869) suggested, and were too numerous for description here, though a means of rapidly recording the position of the lines noted in the Spectroscope, devised by Professor Winlock, proved of too essential service to be left unnoticed. Each spectroscope was provided before leaving America with this attachment, which enabled the observer to record the position of the lines as fast as he could point on them, and with a precision that compared favourably with micrometrical measurement.

I pass to the work done by each observer.

The Spectroscope used by Prof. Young was the one recently described in your pages; and through this he was enabled to watch the occultation of the protuberances of the photosphere, and announce the approach of the moon, some fifteen seconds before "first contact." At this time the sky about the sun was nearly clear, and numerous successive photographs were taken, with the accompanying chronographic record of the instant of exposure. Heavy clouds then obscured the sun, at intervals, till totality was very near, when a happy fortune gave us a few minutes of almost clear sky while it lasted.

It is important to explain that, though the sky was so little obscured that the Corona was visible during the whole of totality, there was during most of this time a very slight haze. I recall a short view of sky, distinctly blue in spite of the darkness; and the structure of the protuberances was continuously visible through the telescope; nevertheless, the presence of this partial haze should be remembered, as having a possible bearing on some of the conclusions to be drawn from what follows.

I give as nearly as I briefly can the principal results of each observer, as regards the corona only.

Professor J. Winlock, using a spectroscope of two prisms on a five-and-a-half-inch achromatic (directed by Mr. A. Clark as the finder) found a faint continuous spectrum, without dark lines.

Of the bright lines, the most conspicuous was 1474 Kirchhoff, which was followed all around the sun to at least 20′ from the disc. It may be here remarked that all the spectroscopes showed this as much the most conspicuous coronal line. A number of other lines were also noted, and their position recorded by the apparatus just referred to.

Professor Young's observations of this line were similar; he estimates its least extension at one half the solar diameter. With the slit of his spectroscope placed tangentially at the moment of obscuration, and for one or two seconds later, the field of the instrument was *filled with bright lines*. As far as could be judged, during this brief interval every non-atmospheric line of the visible spectrum showed bright; an interesting observation, confirmed by Mr. Pye, a young gentleman whose voluntary aid proved of much service. The observation of Mr. Pye was made with a spectroscope of one prism, before which was placed a small telescope arranged at Prof. Young's suggestion, not to give, as usual, a definite image on the slit, but to supply light from all portions of the corona and neighbouring sky with more intensity than would be furnished by directing the instrument toward the sun without it. From the concurrence of these quite independent observations, we seem to be justified in assuming the probable existence of an envelope surrounding the Photosphere, and beneath the Chromosphere usually so called, whose thickness must be limited to two or three seconds of arc, and which gives a discontinuous spectrum consisting of all, or nearly all, the ordinary lines, showing them, that is to say, *bright* on a dark field.

Mr. Abbay, of Wadham College, Oxford, assisted with a Spectroscope prepared by Prof. Young for collateral observations to his own, and obtained results which have already been made public.

The Polariscope was used by Prof. Pickering at a station half a mile distant from the rest of the party. Using successively an Arago Polariscope, one of the form employed by Prazmowski, and a Savart, he is understood to have obtained with all three, results pointing to a radial polarisation of the Corona. The light covering the moon's disc he observed to be polarised throughout in the same plane, and the observations showed that the Arago and other Polariscopes dependent on colour were sufficiently delicate to determine this plane with accuracy.

At the same time Mr. Ross, his assistant, using the instrument employed by Prof. Pickering in the last eclipse, obtained the same results as were then found. Mr. Ross used a modification of the Bunsen photometer, and obtained several concordant measurements, showing that the light was equal to that of a standard candle at two feet.

The writer used a Savart's polariscope attached to a small telescope of $1\frac{1}{2}$ inches aperture, and having a field of about 2°.

The observations with the Savart's polariscope being subject to ready misconception, the preparation for observation and the appearance during it are here given with some minuteness.

Before the eclipse the Savart was so adjusted that the bands were most distinct when vertical, viewing the meridian sun reflected from water. None were visible when the sun was directly scrutinised before or after totality.

During totality the appearance which presented itself was unexpected.

The bands were distinctly seen on the corona, and were brightest where normal to the limb and where tangential to it. As the polariscope was slowly rotated, no marked diminution of their brightness was seen, and when it had been turned through 45° they were as bright as before; distinctly visible even in colour, and they so remained, the rotation being continued for greater security through a whole revolution, during the whole time they presented the appearance described, and characteristic of radial polarisation. They were not noticed on the disc of the moon, but this may well have been from the observer's attention being so exclusively directed to verifying their persistency on the corona.

The writer also employed a good achromatic, of four inches aperture, with a power of about 150, in the direct study of the coronal structure with negative results.

On the closest scrutiny of the part nearest the sun, nothing was seen but a nearly uniform diffuse light, except that one "dark ray" in the field was noticed to be absolutely straight and nearly radial. The outline of the Corona was roughly quadrangular, and a heavy field bar provided for the purpose being carefully set during totality in the direction of the longer diagonal, was found on subsequent estimation to make an angle of as nearly as possible 45° with the vertical.

The "red flames" were beautiful objects, as incidentally noticed during the telescopic scrutiny of the Corona, but not, I may add, more distinctly or more in detail than I had viewed them the day before through the Spectroscope of Professor Young.

The coronal structure is well shown on a photograph obtained by Mr. Willard during totality; a very interesting drawing of it was also taken by Mr. Gordon, a gentleman resident in the vicinity; and all the observers have descriptions to give of its appearance to the naked eye, which differ in some degree from each other. If I compare my impressions with those of others, or even with my own of last year, I find difference enough to suggest the probability of considerable "personality" in all such statements. In some well-marked features all agree, in other minor ones such difference exists that one might almost say each saw a different Corona. The observations with the Spectroscope and Polariscope are happily more removed from uncertainty.

The conclusions reached with both are not perhaps as absolute as they would have been with the cloudless sky of last year's Eclipse, they are still such as to fully justify, we may hope, the cost of labour and time in obtaining them, and which none of those present can regret.

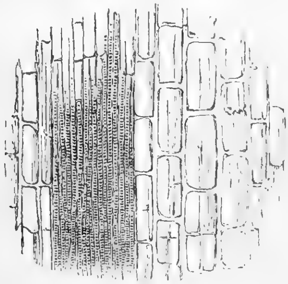
S. P. LANGLEY

SUGAR

II.

THE Beet-root (*Beta vulgaris*) is a native of the south of Europe, and is said to have been introduced into England in 1656. It is a hardy biennial plant with reddish purple leaves and large fleshy roots, which in some varieties are long or spindle-shaped like a carrot, in others short and thick, almost like a turnip. The colour also varies, some forms being of a deep purple, while others are of a dirty white with a purple tinge. Internally the beet-root is of a blood-red colour. It is well known with us both as a pickle and as a salad plant, but it is much more extensively used even for these purposes in Germany and France than it is in England.

Numerous varieties of the beet are in cultivation, but one known on the Continent by the name of Betterave à Sucre is extensively grown as a sugar-producing plant; and the trade in beet-root sugar is a very important one throughout France, Belgium, Germany, and Russia. The bulk of the sugar consumed in these countries is furnished by this plant. Its cultivation for the produce of sugar has been more than once attempted in this country, but hitherto on too small a scale to be successful. Latterly, however, more attention has been paid to it, and more spirit and energy shown by those who have taken up the question towards overcoming obstacles that were at one time considered insurmountable; but whether the results will continue to prove remunerative remains to be seen. So long ago as 1837 a refinery solely for the manufacture of beet-root sugar was established at Chelsea; and many acres of land

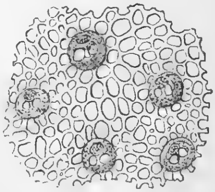


LONGITUDINAL SECTION OF SUGAR-CANE, MAGNIFIED

in the neighbourhood of London were devoted to the cultivation of beet. The discovery of the presence of sugar in beet was made in 1747 by a Prussian chemist named Margraaf, but his discovery was at first considered rather in the light of a scientific than of a practically useful character. It formed the subject of a communication to one of the learned societies in Berlin; and for several years afterwards the sugar so produced was considered an article of curiosity, and was consequently sold at fancy prices. Forty or fifty years elapsed before any experiments were made for the purpose of putting the discovery into practice, with the idea of extracting the sugar for actual use; these experiments however did not succeed, owing to the imperfect manner in which they were carried out; and the beet sugar manufacture would possibly even then have resulted in utter failure, had not Napoleon I., by excluding British Colonial produce from France, rendered it necessary for some new method to be devised for supplying France with sugar. Prizes were offered and many plans submitted. The Government, however, gave its support to the beet as the most likely source of success. Experiments were again renewed, and the result proved satisfactory, so that by 1812 this branch of manufacture was, for a time, placed on a firm footing in France. In 1814, however, the French markets again being opened, large quantities of cane sugar at once appeared from the West Indies, and beet sugar again fell into the background. A system of heavy and increasing duties continued to be levied upon colonial sugar till the year 1822, when the duty became so high as actually to amount to a prohibition to its entrance into French ports, and again the beet-root factories began to flourish. At the present time, or rather before the War broke out, hundreds of millions of pounds were made and consumed. Germany and France produce the largest quantity, Russia following close behind. It is, however, feared that the 300,000 tons of beet-root sugar, which was the estimated produce of France for 1870, will have been for the most part lost, owing to the interruption of the harvesting of the roots, and the consequent stoppage of the operations of the sugar factories.

Like the sugar-cane, the beet varies in quality and in the quantity of saccharine juice, according to the climate, soil, and mode of culture.

After the roots are dug up they are cleaned, usually by scraping them with a knife; they are then either sliced or rasped, and reduced to a pulp, which is placed in canvas bags and submitted to high pressure, by which means the juice is expressed. The pulp undergoes a second and sometimes a third squeezing, so as to obtain all the saccharine matter. This juice or liquor is then heated in a copper, and filtered and boiled with lime and water. A scum rises to the surface, which is taken off, and the juice is again boiled till it becomes of a proper consistency, when it is crystallised in a similar manner to cane



TRANSVERSE SECTION OF SUGAR CANE, MAGNIFIED

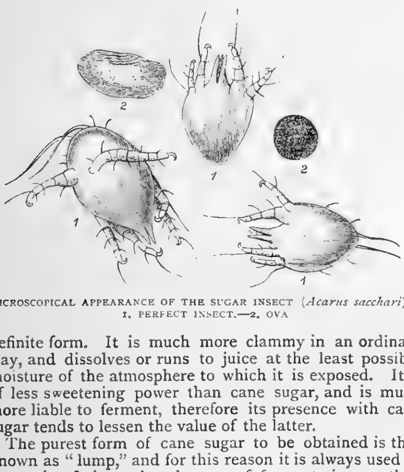
sugar. Beet-root juice as expressed is very clammy to the touch, is nearly colourless, has a strong disagreeable smell, and contains a larger quantity of nitrogenous matter than cane juice. It is capable of being clarified and refined, so that it is made almost, if not quite, equal in appearance to the most superior descriptions of lump or moist sugar prepared from the sugar-cane.

"Beet-root sugar is not only identical with cane sugar, but much of the Dutch lump sugar is actually the produce of beet-root. The circumstance cannot be too much insisted upon, that the seeming distinction between yellow beet sugar and yellow cane sugar depends on the extraneous coloured matters present. These, when eliminated by refining, leave white materials in all respects identical. There is positively no difference between these two, whether of colour or of grain. Grain or crystals can be developed from either to the size of the largest candy if desired; in fact, large white crystals produced from beet-root are sent in quantities from France into this country to compete with London, Bristol, Scotch, and other crystal manufactories."

As beet sugar has become of late in more general use in this country, so has cane sugar found its way in large quantities on the Continent. The mixing of these sugars can scarcely be considered in the light of adulteration, except when an inferior kind of one is mixed with a superior quality of another. The perfect system of filtering adopted in the manufacture of beet-root sugar causes it to be much freer from extraneous matters than cane sugar, small pieces of the cane itself frequently occur in some descriptions of the latter. Of course it is impossible for them to be contained in loaf sugar, sugar-candy, or the finer kinds of sugar which undergo a careful process of purification.

A great deal has been said about the adulteration of sugar with sand, powdered marble, bone-dust, &c., and these tales are readily believed in by many people; but it is very unlikely that such insoluble substances would be used, as they would be sure to be detected. We know that inorganic substances are present in sugar, but we are inclined to believe that they are traceable to the imperfect cleaning of the cane or to the accidents, if we may so call them, attendant upon the process of manufacture.

Amongst the organic impurities often to be found in sugar, besides fragments of the cane before alluded to, are glucose or grape sugar, vegetable albumen, starch, minute fungi, and very frequently a number of small insects known as the sugar beetle (*Acarus sacchari*). The first of these, grape sugar, we have before described as being distinct from cane sugar, though its composition is nearly similar; as it is found most abundantly in grapes, whence its name; but it is also contained in various other fruits, as well in the dried state as in the fresh; and, moreover, it can be produced by the action of dilute sulphuric or other mineral acids, on starch or woody fibre, and so, in short, can be manufactured, which cane sugar cannot. It does not so readily crystallise as cane sugar, and the crystals are irregular, or have no



MICROSCOPICAL APPEARANCE OF THE SUGAR INSECT (*Acarus sacchari*).—1. PERFECT INSECT.—2. OVA

definite form. It is much more clammy in an ordinary way, and dissolves or runs to juice at the least possible moisture of the atmosphere to which it is exposed. It is of less sweetening power than cane sugar, and is much more liable to ferment, therefore its presence with cane sugar tends to lessen the value of the latter.

The purest form of cane sugar to be obtained is that known as "lump," and for this reason it is always used in preserving fruit, as the chances of fermentation are thus diminished. Sugar-candy and all the large crystal or dry sugars are pretty sure to be free from glucose, because its presence would, according to the proportions, cause the sugar to be more or less clammy or moist. The presence of vegetable albumen and starch in cane-sugar is one step towards its conversion into grape sugar or glucose, and consequently increases its inclination to ferment. The removal of this vegetable albumen is one of the objects, as well as one of the difficulties, of perfect sugar refining.

The presence of minute fungi in sugar can only be detected by the aid of a microscope, but the sugar-beetle may be seen with an ordinary lens.

We know of no better way of detecting it along with other impurities than one which has been before recommended, namely, to place a teaspoonful or two of sugar in a glass of tepid water, let it stand till the sugar has completely dissolved, when the insects will be found, some perhaps at the top of the water and others at the bottom amongst the sediment. It is supposed that this insect is the cause of the irritation of the skin, more especially of the hands, from which grocers and those who have the handling of sugar are said to suffer.

Many other plants besides the sugar-cane and beet are used in their respective countries as sugar-producers. Thus, while we and our European neighbours receive our supplies from the two plants just alluded to, the chief sugar-producer in North America is a species of maple (*Acer saccharinum*), a large forest-tree; and in the East Indies several species of palms yield sugar.

With regard to the effects of sugar upon the system, it is abundantly proved that it is most valuable. Nature has so provided that it shall be diffused not only in the sap of young and growing plants, but also in milk, the food of the young of all Mammalia. Though sugar may be considered as a force producer, it is much more adapted to the young than to the adult, for it is not capable by itself of producing muscle.

JOHN R. JACKSON

NOTES

IN addition to the details given this week of the Eclipse Expedition by Mr. Lockyer and Mr. Langley, we have received from Prof. W. G. Adams a report of the Agosta section of the Expedition, publication of which we are compelled to defer till next week.

IT is with great pleasure we hear of the appointment of the Rev. F. W. Farrar to the Headmastership of Marlborough College. This institution has already set an example to our other public schools in the cultivation of Natural Science, which will, we trust, receive a fresh impulse under the new headmastership.

WE rejoice to hear that there is at last a chance of a large amount of scientific knowledge being required at the hands of naval and military officers. This is as it should be, and we earnestly hope that the long-needed reform will not stop here.

THE Austrian astronomers, MM. Weiss and Oppolzer, who went to Africa to observe the Eclipse, were, we regret to learn, as unfortunate as the other observers on that continent.

AT a meeting of the Master and Senior Fellows of Caius College, held December 14, 1870, the following College order was passed:—"That until as many as forty shares of the College income are applied to the promotion of the Natural Sciences and Experimental Physics, a sum equal to the deficit (estimated at 20*l.* a share) be taken from the balance for distribution, and paid to a fund called the 'Natural Science Fund.' That the shares applied to any Fellowship or Scholarship awarded for proficiency in the Natural Sciences and Experimental Physics be counted as so applied. That the Natural Science Fund be applied solely to the promotion of the study of Natural Sciences and Experimental Physics in any way whatever which, in the judgment of the College, may seem proper."

THE Birmingham and Midland Institute has done equal honour to Professor Huxley and to itself, by electing him to the office of President, in succession to the late Charles Dickens.

DR. WOOD has been appointed Lecturer on Chemistry at the St. Mary's Hospital Medical School, in succession to Dr. Russell, transferred to St. Bartholomew's.

WE understand that Dr. Michael Foster and Mr. Watts are engaged in translating Kühne's "Physiological Chemistry."

WE hope in succeeding numbers to give in full Dr. Carpenter's and Mr. Gwyn Jeffreys's Report on Deep-sea Researches carried on during the months of July, August, and September 1870, in the *Porcupine*, recently read before the Royal Society.

WE quote the following pleasant "international" from the *New York Technologist*:—In view of recent remarks concerning the action of the British Government in regard to the expedition proposed by British scientific men, for the purpose of observing the approaching eclipse, it is but justice to say that on proper representation being made to Mr. Lowe, the Chancellor of the Exchequer at once expressed his opinion that such an expedition was one eminently worthy of government aid, and perfect arrangements as regards ships, funds, &c., have been made. One good result has, however, attended this delay on the part of the British Government—it has afforded an opportunity for the exchange of very pleasant courtesies between the scientific men of the United States and those of Great Britain. As soon as Prof. Peirce heard that their government had refused the use of the necessary ships, he at once tendered to the English scientists all the facilities at his command; and they were ample. No one doubts that, under similar but opposite circumstances, the same offer would have come from the other side; for, however stubbornly *Alabama* controversies may hold out, science takes no cognizance of them."

WE are informed that the series of penny lectures on Natural Science, delivered at the Hulme Town Hall, are to be obtained in London of Mr. Pitman, Paternoster Row.

A DEPUTATION from University College, London, consisting of Mr. George Grote, the president, the Hon. George Denman, M.P., Mr. Julian Goldsmid, M.P., and Dr. Storrar, members of the Council; Prof. Fuller, C.E., Prof. Williamson, F.R.S., and Mr. J. Robson, the secretary, has waited upon the Duke of Argyll, at the India Office, to present a memorial from the Council and the Senate of the College, on the subject of the proposed institution of a new Engineering College for the Indian Service. The interview with his Grace lasted upwards of an hour. The memorialists consider that the deficiency in the present system has arisen, not from any defect in the existing places of education, but from the injudicious system of examinations hitherto pursued, and from a want of sufficient inducements to well-qualified men to enter on the career proposed to them. The memorialists assume that the latter cause is recognised by the Government, for it is understood that it is in contemplation to augment considerably the salary upon which a civil engineer in the service of the Indian Government will hereafter commence his work. The memorialists believe the proposed college will be prejudicial to the public service by narrowing the field for the selection of candidates, and by limiting their means of obtaining the requisite instruction. They submit that the working of Government colleges has not been such as to recommend the creation of a new Government college, having practically the monopoly of appointments, and protected from competition. They suggest that such a step is at variance with the plan for throwing open to all Her Majesty's subjects the opportunity of gaining Government appointments.

AT a meeting of the Royal Geographical Society, held on the 9th inst., Dr. Carpenter read a paper on Oceanic Circulation, especially in reference to the inset current into the Mediterranean through the Straits of Gibraltar. After detailing the theories which have hitherto been propounded to account for this current, all of which he pronounced to be unsatisfactory, Dr. Carpenter propounded the following explanation:—The water of the Mediterranean has a uniform but limited excess of weight over that of the Atlantic—so limited as to do away altogether with the idea that there is an accumulation of salt in the Mediterranean. The excess of salt was found to be greater in the lower than in the upper stratum of water, and thus the excess of evaporation was produced. If there be two columns of water of equal density—one that of the Atlantic, the other that of the Mediterranean—an excess of evaporation lowers the height of the Mediterranean column. If the Atlantic column were of fresh water, just enough would flow in from it to restore the evaporated water. But it is salt water which actually flows in from the Atlantic, and therefore it produces an increase of pressure, which presses the Mediterranean water outward till the equilibrium is restored. This being restored, there is once more a reduction of the Mediterranean level by evaporation, and so on; and, therefore, a circulation is always going on between the waters of the Mediterranean and Atlantic. The only difficulty in receiving this explanation is that the water of the outward-flowing current must run uphill; but other examples, he stated, are known. The fact that such a circulation exists, he said, is now indisputable, recent experiments having satisfactorily determined the evidence of a westerly current underlying the surface easterly current. These currents are, therefore, only a portion of the general oceanic circulation, which causes a perpetual surface motion of warm water from the equator to the pole, and a counter under-current of cold water from the pole to the equator. In replying to objections raised in the course of the discussion, Dr. Carpenter said that he had only broken ground in the enunciation of his theory, which it would require much labour yet to work out. Sir Henry Rawlinson, who occupied the chair, stated that in consequence of the continued illness of Sir R. Murchison, he had been appointed president of the Society *ad interim*.

THE Wind-Chart, to which we referred last week, furnished daily by the Meteorological Office to the *Shipping and Mercantile Gazette*, is the invention of Captain Charles Chapman.

FROM the annual report, it appears that the gardens of the Dublin Zoological Society have been very successful, the number of visitors being 136,000, and a considerable balance lies in favour of the society. The donations of axolotls from Prof. Wyville Thomson, and of Mammoth Cave fishes from Prof. Mapother, are acknowledged, but it is not stated if they live or have undergone any developmental changes.

THE following regulations have been issued by the Science and Art Department with regard to science teachers who wish to attend the special (six weeks') courses for training in teaching at South Kensington in June, July, and August, in accordance with the circular of September 1870. These applications are so numerous that it is impossible for the Department to make the selection of teachers to attend, as was originally proposed. The Department has therefore decided to make the selection by competition at the next May examinations. The competition for those who wish to attend the instruction in Biology will be in Animal Physiology, Zoology, Vegetable Anatomy and Physiology, and Systematic and Economic Botany. The candidate may take up all the four subjects, but a fair proficiency in Animal Physiology and in Vegetable Anatomy and Physiology will be essential. If this proficiency is shown, the marks obtained in the other subjects will be counted. By fair proficiency is understood the amount of knowledge required to pass in the advanced stage. For those who wish to attend in Experimental Physics, the competition will be in Acoustics, Light and Heat, and in Magnetism and Electricity. A candidate will be required to take up the honours' papers in those subjects in which he teaches, or in which he is qualified to earn payment, but in any of the other subjects of the group in which he is competing he may take the advanced or the elementary paper. The marks obtained in these subjects will count as in the competition for Royal Exhibitions. The papers of the teachers who are competing will be specially and separately looked over by the professional examiners—the examination being competitive only—and the teachers who answer best, probably to the number of about forty-five in each group, will be allowed to come to London for the six weeks' course of training. They will receive their travelling expenses, namely, second-class railway fare, and 30*s.* a week while in London. The results of the teachers' examination will not be published. Each candidate will be informed of the position in which he would have been placed had he been examined as an ordinary candidate for honours. If he wish his success recorded, it will be done in the ordinary way. The Biology course will commence on the 14th June, and the course on Experimental Physics on the 5th July. It must be understood that no teachers, except such as come up under the foregoing rules, will have travelling allowances under § lxviii. of the Science Directory. No persons are eligible to receive the allowances granted in this minute except those who have been engaged in science teaching under the Science and Art Department during the session 1870-71.

It appears from Mr. Glaisher's Meteorological Tables, that while December 25 was the severest day of the recent frost in the neighbourhood of London, it was still more intense in other localities on January 1, falling as low as 4·9° at Wolverhampton, 5·0° at Hull, 6·7° at Bradford, 7·0° at Leeds, and 9·7° at Leicester, the minimum at Blackheath on that day being as high as 19·2°, although at Twickenham, as reported by Mr. Hall last week, the thermometer fell as low as 6·3°. As on Christmas Day the severest cold was again in the Midland and North Midland counties, and we have once more to record the phenomenon to which we have had occasion to allude more than once recently, that the frost was considerably more intense in England than in Scotland. For the week ending January 7, no lower temperature was recorded at any of the Scotch stations than 21·0°, at Dundee; the mean temperature for all the English stations was 29·6°, while for all the Scotch stations it was 35·5°, or more than 6° higher. From the 20th of December to the 13th of January, when the frost finally broke up, the temperature in London was only even slightly above the mean of the last fifty years on three days.

The Rev. Mr. Gribble, F.R.S., reports from Constantinople that after a fine morning the disc of the sun in the late eclipse was obscured for some time, so that it was not well seen until $3^h 26^m$ mean time, when there was only about one-eighth of the disc clear. A large solar spot then became uncovered; clouds coming on again, this was all that was seen clearly. At $3^h 26^m$ the light was considerable.

The *Scottish Naturalist*, to which we referred some weeks since as a new periodical proposed to be issued under the auspices of the Perthshire Society of Natural Science, has made a good beginning. Opening with a short programme of future operations, in which the editor, Dr. Buchanan White, wisely states his intention of restricting the contributions to papers and notes especially bearing on Scottish Natural History; we then have an article by Dr. Lauder Lindsay "On Natural Science Chairs in our Universities," to which we may possibly take occasion again to refer. The writer deals with a bold hand with the evils which are said to prevail more especially in the election of Professors in our northern Universities. He refers to the manner in which these appointments are stated often to be regulated by political influence or religious belief rather than by possession of qualifications to teach Natural Science, and is especially severe on the system of personal canvass and the "testimonial nuisance." Mr. J. A. Harker contributes a paper "On the Work and Influence of Local Natural History Societies;" Mr. George Norman a List of the Noctuæ occurring in Morayshire; the editor some hints on Sugaring, how, when, and where to do it; and an anonymous contributor, a paper "On the Mollusca of the North-east of Scotland," illustrated with a map. Some shorter articles and notes with reports of proceedings of Scottish Natural History Societies, make up the number, which we commend to the notice of all interested in natural history across the Border.

HENDERSON'S PATENT PROCESS FOR REFINING CAST-IRON

An article was furnished a short time ago, and published in Nature (No. 57, p. 94), respecting a new process for the production of steel by the partial decarburisation of cast-iron, invented by the writer. It was then stated that a description of a new process for refining cast-iron would soon follow.

This process supplies a more effective and economical process than the English finery or the German reverberatory furnace processes for refining cast-iron. It is very simple, and does not require any fuel, labour, or expensive apparatus; and there is no loss of weight of iron, as the impurities go off in vapour. The cost of refining is less than one-twentieth of that of the English and German processes; and its effect is more thorough than is possible by those systems.

The agents used are fluorine and oxygen combined. The fluorine is derived from any fluoride, and the oxygen from any substance containing or capable of evolving oxygen, which is adapted to use in the manufacture of wrought-iron and steel. Fluorspar and pure rich iron ores are the most available and economical substances for producing these agents, and are applied finely powdered and mixed, and placed in receptacles, preferably, so as to act from the under side upwards upon cast-iron in its molten state.

The most economical mode of application of this process is to treat the cast-iron in the condition in which it flows from the blast furnaces, with fluorspar and iron ore, applied in the "chills" or pig moulds used at blast furnaces, by being spread over the bottom of the moulds.

The iron, when tapped from the blast furnace, flows into the mould thus prepared; the heat of the iron causes fluorine and oxygen to be liberated, and, by reason of the affinities of these substances for silicon and phosphorus, these impurities are removed in the form of *vapour*. The reactions in the "chills" are similar to those of the boiling puddling process, and last about five minutes. The metal during this period is covered with jets of flame and smoke. The resulting metal, with respect to silicon and phosphorus, is as pure as wrought-iron.

It is preferable to use iron ores containing the largest amount of oxygen and the least of silica and phosphorus. These conditions exist in "washed iron sands," and the red hematites of Cumberland and Lancashire. When using the hematite ores, varieties that are the easiest to reduce to powder are preferred; and the ordinary edge running apparatus, with cast-iron rollers revolving in a pan, is an excellent one for the purpose.

The fluorspar and fine ore are passed through a sieve of not less than four hundred meshes to the square inch, and afterwards mixed so thoroughly as to appear to be one substance, in the proportion of one part of fluorspar to two parts by weight of iron ore, and are spread one-fourth to three-eighths of an inch deep over the "chills," then the iron is run upon them so as to form slabs one inch thick.

The former article gave analyses of refined cast-iron produced in the reverberatory furnace. It will be seen by comparing the analysis of the refined metal of this process with the analysis of that of the reverberatory furnace process, that they are analogous, except that the latter contains no silicates or graphite. The refined metal of the pig-mould process saves the fuel and time taken for refining by the reverberatory furnace process, and shortens the time of producing steel or wrought-iron by that process fully forty minutes. When using the refined metal of this process two workmen can take charge of five ordinary boiling puddling furnaces making steel, and six furnaces making wrought-iron, as the only labour necessary is "balling" and removing it from the furnace. When high carburised steel is made, "balling" is not required, as the metal will be fluid enough to run from the furnace into ingot-moulds. The economy of the process consists in the saving of the labour of eight workmen making steel, and two workmen making wrought-iron; and in the superior quality of the result as compared with puddling the refined metal. The time occupied by the conversion of the refined metal into steel or wrought-iron by the process without puddling is about the same as that usually taken in puddling pig-iron.

Ordinary coke pig-iron, smelted near Pittsburgh from a mixture of hematite ore and mill cinder, has been treated by this process. The refined metal was afterwards puddled and rolled into "muck" bars, and once heated and rolled into merchant bar-iron. The pig, refined cast, and wrought-iron, have been analysed by an analytical chemist in this city. These analyses are annexed, also analyses of refined cast-iron by the English finery and German reverberatory furnace process, and of the highest standard qualities of English, French, Swedish, and Russian wrought-iron, are given for comparison, taken from Percy's "Iron Metallurgy" and Ure's Dictionary:

	Pittsburgh Coke Pig-iron.	Patent Refined Cast-iron.	Bar-iron.
Carbon (combined)	0·2040	0·3613	not deter.
do (graphite)	2·7685	2·5066	—
Silicon	2·3096	none	none
Slags (silicates)	0·3623	0·2983	not deter.
Phosphorus	0·4196	0·1029	0·0087
Sulphur	0·1298	0·1269	0·0438

Analyses of Foreign Iron.

	English Finery Process. Refined Cast-iron.	German Reverberatory Furnace Process. Pig-iron.	German Reverberatory Furnace Process. Refined Cast iron.
Carbon	3·07	—	—
Silicon	0·63	4·66	0·62
Phosphorus	0·73	0·56	0·50
Sulphur	0·16	0·04	0·03
Silica, Alumina } Silicates	0·44		

	English Wrought-iron. Low Moor Stamp.	French. Petin, Gaudet, & Co.	Swedish. Hoop L.	Russian. C C N D
Carbon	0·016	0·143	0·087	0·272
Silicon	0·122	—	0·115	0·062
Sulphur	0·104	0·058	0·220	0·234
Phosphorus	0·106	0·030	0·034	—

On comparing the analysis of the refined cast-iron of the patent process with those of the English and German processes, it will be seen that while the refined iron of the new process contains *no silicon*, that of the English and German processes contains 0·63 and 0·62 per cent. respectively; and compared as regards phosphorus, the German process reduces it from 0·56 to 0·50 per cent., or about 0·06 per cent., and the new process reduces it 0·32 per cent., or over five times as much phosphorus is removed by the new process as by the other processes. The slags or silicates are 0·15 per cent. less than in the refined iron of the English finery process. The analysis of the patent refined cast-iron, compared with that of the above English wrought-iron, shows that whilst the wrought-iron contains 0·122 per cent. of silicon, the refined metal contains none, and compared as regards phosphorus they are about the same.

The analysis of the puddled wrought-iron, made from the refined cast-iron by once heating and rolling the puddled or "muck" bar, shows a purer quality of iron than the most celebrated makers of Europe produced from the purest ores with charcoal.

The economy of using the refined metal in saving cost of labour, fuel, &c., for the puddling process, has been fully demonstrated by numerous trials. When all the advantages of the process are realised, about one-half of the cost of converting cast-iron into wrought-iron can be saved; and there is an improvement in the quality equal to the difference between ordinary forge pig-iron and charcoal iron.

These advantages are:—

1. Better quality, which is due to the purity of the refined metal; as good qualities of wrought-iron are produced from it as from pig-iron made from the best ores smelted with charcoal.

2. The refined metal being as pure as wrought-iron, with respect to silicon and phosphorus, requires merely decarbonising, with less skill to work it, and greater certainty of the quality of the product.

3. Large saving in cost of production, owing to the shortening of the time of puddling, which is caused by the removal of a large part of the impurities by the refining process. White refined iron is decarbonised in twelve to fifteen minutes, and a "heat" or charge of five hundred pounds is puddled in fifty-five minutes, including time of charging, melting the iron, and stirring or puddling or "balling" and removing it from the furnace; grey forge iron requires sixty-five minutes, and foundry iron about seventy minutes. Seven "heats" or charges to a "turn" or a day's labour, are of easier accomplishment than five charges are from the pig-iron from which it was produced; the five charges now require ten hours to convert pig-iron into wrought-iron. It is possible to obtain, with the patent refined metal, by employing three sets of workmen in twenty-four hours, instead of two sets as is now customary, twenty-one charges in twenty-four hours instead of ten charges; and allowing sufficient time for repairs, the production of any ironwork may be doubled, without additional investment of capital and without additional cost of repairs.

4. Saving of fuel per ton of iron produced, amounting to one-half, caused by increased production.

5. Reduction of general business expenses per ton of iron, amounting to one-half, caused by increased production.

6. Reduction of wages, by reason of the diminished labour, of 40 per cent. per ton of iron.

7. The puddling furnace cinders of the refined metal contain but about one-fourth of the phosphorus, as compared with the cinders resulting from the use of pig-iron; and when smelted produce better qualities of pig-iron.

The cost of refining in the pig-moulds is very little. Fluorspar is a cheap material, and but about seventy pounds are required to refine a ton of iron. The cost is nearly compensated by the saving of the fuel and lime which would be required to reduce the puddle cinders of the refined cast-iron to pig-iron, as they contain but small portions of silica, and will require less fuel and limestone. The residue of the fluorspar and oxide is agglutinated, and remains in the pig moulds, and is pure lime and deoxidised iron ore, and is available as so much lime and ore in the blast furnace. JAMES HENDERSON

SOME EXPERIMENTS ON COLOUR

THE theory of colour perception, although in England it has not yet made its way into the text-books, still less into the popular works on science, is fully established with regard to many important points. It is known that our perception of colour is threefold, that is, that any colour may be regarded as made up of definite quantities of three primary colours, the exact nature of which is, however, still uncertain. More strictly stated, the fundamental fact in the doctrine of colour is that, between any four colours whatever given, as well in quantity as in quality, there exists what mathematicians call a linear relation, that is, that either a mixture of two of them (in proper proportions) can be found identical, so far as the eye is able to judge, with a mixture of the other two, or else that one of them can be matched by a mixture of the other three. There are various optical contrivances by which the mixture spoken of may be effected. In the year 1857, Mr. Maxwell published an account of some experiments with the colour top undertaken to test the theory. From six coloured papers, black, white, red, green, yellow, and blue, discs of two sizes were prepared, which were then slit along a radius so as to admit of being slipped one over the other. Any five out of the six being taken, a match or colour equation between them is possible. For instance, if yellow be excluded, the other five must be arranged so that a mixture of red, green, and blue is matched with a mixture of black and white. The large discs of the three colours are taken and slipped on to each other, and similarly the small discs of black and white. When the small discs are placed over the others and the whole made to rotate rapidly on any kind of spinning machine, the colours are blended, those of the large discs and those of the small, each into a uniform tint.

By adjustment of the discs an arrangement may be found after repeated trials, such that the colour of the inner circle is exactly the same both in tint and luminosity with that of the outer rim. The quantities of each colour exposed may then be read off on a graduated circle, and the result recorded. For instance (the circle being divided into 192 parts), eighty-two parts red mixed with fifty-six green and fifty-four blue, match thirty-seven parts white mixed with 155 black. In this way Maxwell observed the colour equations between each set of five, in all six sets formed by leaving out in turn each of the six colours. Moreover, for greater accuracy each set was observed six times, and the mean taken. But according to the theory these six final equations are not all independent of each other, but if any two of them are supposed known, the others can be found by a simple calculation. Accordingly, the comparison of the calculated and observed equations furnishes a test of the theory; but in practice, in order to ensure greater accuracy, instead of founding the calculations on two of the actually observed equations chosen arbitrarily, it is preferable to combine all the observations into two equations, which may then be made the basis of calculation. In this way, a system of equations is found necessarily consistent with itself, and agreeing as nearly as possible with the actually observed equations. A comparison of the two sets gives evidence as to the truth of the theory according to which the calculations are made, or if this be considered beyond doubt, tests the accuracy of the observations. In Maxwell's experiments the average difference between the calculated and observed systems amounted to ·77 divisions of which the circle carried 100. So good an agreement is regarded by him as a confirmation of the whole theory; but it seems to me, I confess, that only a very limited part of it is concerned. The axioms, in virtue of which it is permitted to combine the colour equations in the manner required for the calculations, are only such as the following:—If colours which match are mixed with colours which match, the results will match. It is difficult to imagine any theory of colour which will not include them. What proves the threefold character of colour—the most important part of the doctrine—is simply the fact that with any five-coloured papers *whatever* a match can be made, while with less than five it cannot (except in certain particular cases). In regard to this point the value of the quantitative experiments is rather that they show of what sort of accuracy the eye is capable in this kind of observation. Those to whom the subject is new may think at first that if colour be threefold a match ought to be possible between any *four* colours. And so it is possible if there is no other limitation; but in experiments with the revolving discs, we are subject to a limitation, being obliged to fill up the whole circumference somehow. The difficulty will clear itself up, when it is remembered that one of the five colours may be black, so that with any *four* colours and *black* a match can be made with revolving discs.

It was rather for my own satisfaction than with the hope of adding anything new to a subject already so fully and ably treated by Maxwell, that I commenced a repetition of his experiments. The colours used were, roughly speaking, the same as his, as was also the general plan of the observations. The agreement of the calculated and directly observed equations was very good, the average error being only ·24 divisions of which the complete circle contained ninety-six, or one-third of the corresponding average error in Mr. Maxwell's Table. A second set of observations and calculations made after a year's interval with a different set of colours gave about the same result. I am inclined to attribute the considerably greater accuracy of my observations rather to an excellent perception of minute differences of colour (to which I have always found my eyes very sensitive) than to greater care in conducting the experiments. One precaution, however, I have found so important as to be worth mentioning. Unless the small discs are very accurately cut and centred, a coloured rim appears on rotation between the two uniform tints to be compared and adjusted to identity, which is exceedingly distracting to the eye, and interferes much with the accuracy of the comparison. One set of observations made with the same care, and apparently as satisfactory as any of the others, puzzled me for some time on account of the great discrepancies with the others which it exhibited. I have no doubt that the cause lay in the different character of the light on the day in question, which came from the unusually blue sky which sometimes accompanies a high wind. On the other days the light came principally from clouds. I have had no opportunity of confirming this opinion by a repetition of the experiment with a sky of the same degree of blueness, but that the disagreement was not the result of unusually large errors of observation, is, I think, to be inferred from the fact that the observations under the blue sky were as consistent among themselves as any of the other sets. As the point is of some interest, I give the figures in full.

July 23, blue sky.

Black.	White.	Red.	Green.	Yellow.	Blue.

The numbers read off for the big discs are written with the sign + prefixed, and those corresponding to the little discs with —. Thus the first line may be read: — 30 parts white together with 122 red and 40 green, match 77 yellow and 115 blue. The upper line of each pair represents the actual observation, and the second is the theoretical equation calculated from two in the manner described. The average difference between the two sets of numbers which may be taken as a measure of the inaccuracy of the observations amounts to 1·1. A similar table, formed from the observations of July 20 (cloudy), and which agreed very well with the results of other days, is as follows*:—

Black.	White.	Red.	Green.	Yellow.	Blue.
0	+ 30	+ 117	+ 45	— 79	— 113
0	31·1	116·2	44·8	79·9	112·2
+ 90	0	— 128	— 64	+ 56	+ 46
85·9	0	128·4	63·5	57·0	49·0
— 136	— 56	0	+ 22	+ 52	+ 118
137	55	0	22·3	50	119·6
+ 100	+ 50	+ 42	0	— 64	— 128
99·2	51	41·9	0	65	127·1
+ 135	+ 21	— 123	— 69	+ 36	0
135·7	21·5	122·7	69·3	34·8	0
— 152	— 40	+ 80	+ 56	0	+ 56
152·6	39·5	81	56	0	55

The average error is here ·95, showing only a trifling better agreement than the former set, so that the blue sky observations are nearly as self-consistent as those made with cloud-light. Moreover, the agreement is itself very good, being decidedly better than Maxwell's, though his calculations refer to a *mean* of six sets of observations.

While therefore there is no reason to distrust the results of July 23 any more than of July 20, the differences between them are much greater than can be ascribed to errors of observation. It will be found that they relate principally to the quantities of red, the numbers under that head being considerably greater for the case of the blue light from the sky. I am not aware whether the difference of sky and cloud light has ever been made the subject of direct investigation, but it would seem a fair inference that it must consist mainly in a relative deficiency of the red rays. If this be so, as I have other grounds for suspecting, the light of the

* These calculations were made by means of Prof. Everett's Proportion table, which seems admirably adapted to work of this sort.

sky would be similar in composition to that of dilute solutions of copper, which acquire their light blue tint by a partial suppression of the extreme red.* There is no doubt that the colour equations are dependent on the character of the light, as may easily be proved by taking an observation looking all the time through a layer of coloured liquid. It is not, however, the most brilliantly coloured solutions that cause the most disturbance, for anything like a complete stoppage of all the rays which are capable of exciting one of the primary colour sensations would affect both the mixtures to be compared in nearly the same manner, putting the observer in fact very much into the positions of a colour-blind person. Those liquids will be most efficient which have a different action on parts of the spectrum allied in colour. For instance, an aqueous infusion of litmus has a strongly marked action on the yellow ray, stopping it with great energy, even in rather dilute solutions. It is easy to trace the effect of looking through this on most of the colour equations. Consider, for example, the fifth equation of July 20 (that from which the blue is absent) wherein red and green are matched against black, white, and yellow. The red and green will for the most part escape absorption, but the white and yellow will be shorn of a part of their yellow rays. The match supposed to have been adjusted without the litmus must evidently be spoiled; the red and green mixture becoming strongly yellow in comparison with the other. In order to restore equivalence the yellow must be considerably increased. On trial I found, 124 black + 19 white + 49 yellow matched 121 red + 71 green.

It is only the impurity of the colours on the discs that prevents the effect being still more strongly marked, for with the pure colours of the spectrum the most violent alterations are possible. When a match is made between the simple yellow and that compounded of pure red and green, almost any coloured liquid acts unequally on the two parts and destroys the balance. The simple yellow, of course, retains its colour under any absorbing influence, and can only be changed in luminosity. Chloride of copper extinguishes the red component of the compound yellow, which accordingly becomes green. Litmus would leave the compound colour nearly unchanged, while it extinguishes the simple yellow. It is needless to multiply instances.

Before leaving the compound yellow, of whose very existence many are incredulous, I will mention an easy way of obtaining it, which is the more desirable as the use of the pure spectral colours is not very convenient. In order to isolate the red and green rays of the spectrum by means of absorption, the first thing is to find a liquid capable of removing the intermediate yellow and orange. With this object we may fall back on the alkaline solution of litmus, whose opacity to the yellow, and particularly to the orange rays is so marked. The next step is to remove the blue and bluish green, for which nothing is more convenient than the chromate of potash. A mixture of these two liquids in proper proportions, easily found by trial, isolates the green and extreme red rays with considerable perfection, and exhibits in a high degree the phenomenon of Dichromatism. According to the thickness traversed by the light the red or the green predominates, and there is no difficulty with a given thickness in arranging the strength of the solution so as to give a full compound yellow. It is worth notice in confirmation of the opinion expressed as to the character of the sky-blue, that when a cloud seen through the liquid appears a full yellow, or even orange, the former, if at all intense, acquires a decided green colour. A window backed by well-lighted clouds, when looked at across a room through the liquid and a prism, has a very splendid appearance, the red being isolated on one side, and the green on the other; while the intermediate space, where the two overlap, shows the compound yellow in great perfection. Another liquid, in some respects preferable, which answers the same purpose, may be made by mixing chloride of chromium and bichromate of potash. Through either of them the sodium flame is invisible, though they may easily be made to correspond with it in colour very closely. I tried to obtain a liquid capable of isolating the pure yellow ray, but only with partial success. The best was a mixture of bichromate and permanganate of potash with a salt of copper (sulphate or chloride). The first removes the blue and violet, the second the green, and the third the red, and thus the yellow is isolated in considerable purity. This liquid is very unstable. The comparison of the simple and compound yellow (which nearly matched) was interesting. One was transparent to the sodium flame, the other completely opaque to it. When the two are brought together so that the light has to traverse both, almost complete darkness results, even when the brightest clouds are used. I should mention that it is only when the light is strong that any of these liquids give yellow in full perfection; otherwise the colour is more nearly described as brown, which is, in fact, identical with a dark yellow or orange. The best natural yellows, such as chrome, are partly simple and partly compound, returning all the light which falls upon them except the blue and violet. It is clear that neither a purely simple nor a purely compound yellow can rival them in brilliancy.

Impartial observers, unprejudiced by the results of mixing pigments, or, on the other hand, by experiments on the spectrum, see, so far as I can make out, no connection between the four principal colours—red, yellow, green, and blue. It seems to them quite as absurd that yellow should be compounded of red and green, as it most unquestionably is, as that green should be a compound of blue and yellow, though many have accepted the latter alternative on the authority of painters, and some have even worked themselves into the belief that it is only necessary to look at the colours in order to recognise the compound nature of green. My own prejudice would be on the other side, the result of experiments on the compound yellow, which is seen so easily to pass into green on the one side or red on the other. The most impartial opinion that I can form is that there is no real *resemblance* between any of the four, and if this be so it is certainly a most remarkable, if not unaccountable, fact. The difficulty is not so much that we are unable to analyse the compound sensation, as to explain why our inability is limited to yellow (and white). For everyone, I imagine, sees in purple a resemblance to its components red and blue, and can trace the primary colours in a mixture of green and blue. Sir John Herschel even thinks that our inability to resolve yellow leaves it doubtful whether our vision is trichromic or tetrachromic, but this seems to me to be going much too far. Surely the fact that the most saturated yellow can be compounded of red and green, deprives it of any right to stand in the same rank with them as primary colours, however little resemblance it may bear to them and blue. Besides, if yellow is to be considered primary, why not also white, which is quite as distinct a sensation as any of the others? Undoubtedly there is much that is still obscure in the mutual relations of the colours—why, for instance, as mentioned by Sir John Herschel, a dark yellow or orange suggests its character so little as to be called by a new name (brown), while a dark blue is blue still. But difficulties such as these should make us all the more determined to build our theories of colour on the solid ground that normal vision is threefold, and that the three primary elements of colour correspond nearly with red, green, and blue.*

J. W. STRUTT

* Direct observations, made since the above was written, show that there is no *peculiar* deficiency at the red end of the spectrum, but a general falling off as the refrangibility diminishes from one end to the other. If lights from sky and cloud are of equal intensity at the line C in the red the first will be somewhere about twice as bright as the other at B in the green. This is for a well-developed blue light taken from the zenith; but, even with a large allowance, enough difference remains to account for the discrepancies in the two sets of colour disc observations. I have lately found from theory that the power of very small particles to scatter the rays belonging to different parts of the spectrum varies as the inverse fourth power of the wave length

SCIENTIFIC SERIALS

THE *Quarterly Journal of Science* for January commences a new *régime* under the sole editorship of Mr. W. Crookes. As will be seen from the following summary of its contents, all the papers, with only one exception, refer to some department of Physical Science to the exclusion of Natural History. The articles are as follows:—1. "Double Spectra," by W. M. Watts. A *résumé* of the facts known to the present time to modify the conclusions drawn from the earlier spectrum researches of Bunsen and Kirchhoff, from which it was concluded that the spectrum of each element was one and invariable. A plain and a coloured lithographic illustration show the spectrum of copper chloride when volatilised undecomposed, as contrasted with that of the metal; the different spectra of barium, strontium, and calcium obtained at different temperatures; the three spectra of hydrogen, $H\alpha$, $H\beta$, and $H\gamma$, probably due to differences in temperature; the two spectra of aluminium; the two of nitrogen; and the four spectra which are all probably due to incandescent carbon vapour. 2. "The Great Pyramid of Egypt, from a modern scientific point of view," by C. Piazzi Smyth, Part I. 3. "On the Theory of

Irrigation," by F. C. Danvers. An account of the advantages that would result to agriculture from a system of irrigation, rendered necessary by the destruction of forests, irrespective of the question of the utilisation of sewage. 4. "War Science," by H. Baden Pritchard. A statement of the instruction in War Science given in the Royal Artillery and Royal Engineers, and of recent improvements in gunnery, illustrated especially by the Scott and Moncreiff gun-carriages; the improved modes of manufacturing gunpowder; and the invention of the electric torpedo in conjunction with the Abel fuse. 5. "Spectra of Metallic Compounds," from the Journal of the Franklin Institute. 6. "On the various Tints of Autumnal Foliage," by H. C. Sorby. A very interesting paper, in which the writer details the results of his experiments on the various colouring matters of leaves, &c., which he classifies as follows:—(1) *chlorophyll*, or the green colouring matter; very rarely found pure, even in fresh leaves; insoluble in water, but soluble in alcohol or bisulphide of carbon; the spectra have all a very well-marked absorption band in the red, but the green is more or less completely transmitted, so that the prevailing tint is a more or less modified green; (2) the *xanthophyll*, or yellow group; insoluble in water, but soluble in alcohol and in bisulphide of carbon; the spectra show absorption at the blue end, often with more or less well-marked narrow bands; but the red, yellow, and yellow-green are freely transmitted, so that the general colour is clear yellow or orange; (3) *erythrophyll*, or the red colouring matter; soluble in water and aqueous alcohol, but not in bisulphide of carbon; show strong absorption in the green part of the spectrum; (4) *chrysophyll*, or the golden-yellow group; soluble in water and aqueous alcohol, but insoluble in bisulphide of carbon, with variable spectra; (5) the *phaiophyll* group, comprising various browns; soluble in water, but not in bisulphide of carbon; do not give well-defined absorption-bands. Mr. Sorby gives the following scheme of the relative abundance of these various groups of colours as the leaves advance towards decay.

Complete vitality and growth . .	Chrysophyll . .	More or less bright green.
	Chlorophyll . .	More or less green-brown.
Low vitality and change . . .	Erythrophyll . .	More or less red-scarlet.
	Xanthophyll . .	More or less bright orange-brown.
Death and decomposition . .	Phaiophyll . .	Less or more dull brown.
	Humus	

7. "On the Relations between Chemical Change, Heat, and Force, with a special view to the economy of electro-dynamic engines," by the Rev. H. Highton. Contests the theory generally accepted that a certain amount of chemical change corresponds and is interchangeable with a certain amount of heat and electric force; and that this heat again corresponds and is interchangeable with a certain amount of work or mechanical energy. The author considers that the whole subject requires a fresh, strict, and full experimental investigation. He then refers to the many different answers that have been given to the question, What is the mechanical equivalent of heat? and holds that it has never been proved that there is any such equivalent. He details in support of his view the conflicting results obtained from the elaborate experiments with a galvanic battery by such experimenters as M. Favre, M. Sorel, M. Weber, M. Kohlrausch, and Mr. Gore. 8. "Our Patent Laws."—The pages devoted to "Progress of the Sciences" again embrace Physical Science only, Physics, Chemistry, and Mechanics—an inequality which will doubtless be rectified in future numbers.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, January 12.—"Some Experiments on the Discharge of Electricity through Rarefied Media and the Atmosphere." By C. F. Varley.—After the labours of Mr. Gassiot, one approaches this subject with diffidence, lest he should appear to be attempting to appropriate the glory which so justly belongs to that gentleman and to Professor Grove. The nature of the action inside the tube is at present involved in considerably mystery, but some light is thrown upon the subject by the following experiments. Before describing them, however, the author wishes to observe that he has seen Mr. Gassiot's last papers,* and finds that, so far as regulating the strength of the current is concerned, he has been proceeding in a similar manner to the author. The tube principally used in these experiments contains two aluminium wire rings, the one $\frac{4}{10}$ inch in diameter, the other $\frac{9}{10}$, and separated $\frac{8}{10}$ inch, the tube $1\frac{1}{4}$ inch in diameter, $3\frac{1}{4}$ inches in length; it was one of Geissler's manufacture, was very well exhausted, and professed to contain hydrogen. A U-shaped glass tube containing glycerine and water was placed in circuit. Two aluminium wires inserted in this tube gave a ready means of reducing or augmenting the resistance at pleasure. Glycerine affords an easy means of producing very great resistances. The battery used in this experiment was a Daniell's battery, each cell having a resistance of from 50 to 100 Ohms. The resistance of the glycerine-and-water-tube was between 2 and 3 megohms; this latter resistance was made large, in order that the resistance of the tube and battery might be neglected without entailing error. The following law was found to govern the passage of the current:—1st. Each tube requires a certain potential to leap across. 2nd. That having once established a passage for the current, a lower potential is sufficient to continue the current. 3rd. If the minimum potential, which will maintain a current through the tube, be P, and the power be varied to $P+1$, $P+2$, &c. to $P+n$, the current will vary in strength, as 1, 2, &c. n. The following Tables (I. and II.) illustrate this; there is a little irregularity in the figures due to the irregularity of the battery, although it was recharged for the occasion.

It thus appears that a certain amount of power is necessary to spring across the vacuum; after that it behaves as an ordinary conductor, excluding that portion of the battery whose potential is P, and which is used to balance the opposition of the tube. In these experiments P was 304 cells. The tube in question could not be persuaded to allow a current of less than 323 cells to pass; but when once the current had established a channel, on lowering the potential by *short circuiting* portions of the battery, so as not to break the circuit, the current would flow when the battery was reduced to 308 cells. By, however, passing a current from 600 cells through the second tube W, filled with pure glycerine, and offering several thousand megohms resistance, an extremely feeble current, too weak to affect the galvanometer, kept a channel open by its passage; with this arrangement the figures in Table II. were obtained, which are more regular at the commencement, and a power of $P+1$ would pass

* Proc. Roy. Soc., vol. xi. p. 329, & vol. xii. p. 329.

* This power, 323, was the lowest at which the current would jump.

across the tube. The positive pole alone was observed to be luminous when the current was very minute, and the negative only was luminous when the current was strong. The following experiments were tried, and the results, which have been photographed, accompany the paper. A current was passed through the tube U and the vacuum; the U tube contained pure glycerine, and had a very large resistance, which was gradually reduced. At the commencement it was more than 10,000 megohms; the upper or small ring was positive, the lower ring was negative. The power was so reduced that the faintest possible light only was visible; in this case the positive wire alone was luminous, whether it were the large or small ring that was positive. The light was so feeble that, though the experiment was conducted in a perfectly dark room, we were sometimes unaware whether the current was passing or not. An exposure of thirty minutes' duration left, as will be seen, a very good photographic record of what was taking place; this means of viewing light too feeble for the eye may receive other applications. The resistance was then reduced, when the light became much more brilliant,—a tongue of light projected from the positive pole towards the negative, the latter being still almost completely obscure. The light around the positive pole was to all of our eyes white, while the projecting flame was a bright brick-red. This bright brick-red, however, possessed great photographic power. The negative wire at this stage began to show signs of luminosity. As the power was increased, the flame became detached from the positive pole. On still further increasing the power, the positive pole ceased to be luminous; and on still further increasing the power, by removing the U tube altogether, the light surrounded the negative wire, the photograph shows a white flattened hour-glass, apparently detached from the wire; to the eye, however, the wire appeared to be surrounded by a bright blue envelope $\frac{1}{4}$ inch in diameter, which did not possess sufficient photographic power to leave a record of itself, while the red portion did so. A large condenser was now attached to the battery, and discharged through the tube (the condenser had a capacity of 27 microfarads); this was equivalent to a momentary contact with a battery of little or no resistance. The flash was exceedingly brilliant to the eye; it could be heard outside the tube with a sharp click; the eye, however, was so dazzled as not to be able to see its shape. The light was confined entirely to the *positive pole;* thus, then, as the power is increased from nothing upwards, the first pole to become luminous is the positive; secondly, the two poles become luminous; thirdly, the negative pole alone is luminous; and fourthly, with an instantaneous discharge, the positive pole only is luminous. When the resistance in the U tube was greatly reduced, and a galvanometer (not very sensitive) was inserted, so that the chief resistance in circuit was that of the exhausted tube, as the potential was augmented cell by cell, the changes took place abruptly and suddenly. For example, when the power was so low that the positive pole only was visible, the current was feeble, and kept augmenting in power as cell after cell was added on. Suddenly the luminous red flame made its appearance, and the galvanometer showed that the current had suddenly augmented three or four times in power. As the power was again further increased, cell by cell, the current again steadily augmented in proportion, until the luminous tongue suddenly disappeared, the galvanometer showing a still further sudden increase in the current.

Nature of the luminous cloud.—Plücker has shown that when such an exhausted tube, with a current through it, is placed between the poles of an electro-magnet, a luminous arch is produced, which arch follows the course of the magnetic rays. As the electro-magnet is magnetized, the tube, which before was full of a luminous cloud, is seen gradually to change; the magnet gathers up this diffused cloud, and builds up an arch. Inasmuch as the electricity was passing in a continuous current from the battery, from wire to wire, it is evident the light is projected right and left into those parts of the tube where there is no electric current flowing. To endeavour to ascertain the nature of this arch, a tube was constructed. A piece of talc, bent into the form U, had a fibre of silk stretched across it; on this fibre of silk was cemented a thin strip of talc, 1 inch in length, $\frac{1}{10}$ inch broad, weighing about $\frac{1}{10}$ of a grain. The tube was sealed up and exhausted; carbonic acid and potash were used to get a high vacuum. When the magnet was not magnetized, the passage of the current from wire to wire did not affect the piece of talc. When the magnet was charged, and the luminous arch was made to play upon the lower portion of the talc, it repelled it, no matter which way the electric current was passing. When the tube was shifted over the poles of the magnet so as to project the luminous arch against the upper part of the talc, the upper end of the talc was repelled in all instances; the arch, when projected against the lower part of the talc, being near the magnet, was more concentrated, and the angle of deviation of the talc was as much as 20°. When the upper part of the arch, which was much more diffused, was thrown upon the upper part of the talc, it was repelled about 5°. This experiment, I think, indicates that this arch is composed of *attenuated particles of matter projected* from the negative pole by electricity in all directions, but that the magnet controls their course, and these particles seem to be thrown by momentum on each side of the negative pole, beyond the limit of the electric current. This arch requires time for its formation, for when a charged condenser is discharged through the tube no arch is produced. The arch from the negative pole is a hollow cylinder; the little talc tell-tale against which the arch was projected cut out the light, and a corresponding dark space existed throughout the remainder of the course of the arch. There was on the talc, at the spot where the arch struck it, a little bright luminous cloud, as though the attenuated luminous vapour was condensed by this material obstruction. Great care had been taken not to let the arch strike the single filament of silk which suspended the talc. Having demonstrated that the talc was repelled as described, the arch was allowed to play against the silk fibre, which the author expected would have been instantly burnt; such, however, was not the case. Even when a powerful induction-coil replaced the battery, the fibre remained unhurt.

Comparison of the above phenomena with discharges between the poles of a Holtz's Machine in air.—In the first part of this paper four different kinds of discharges were described *in vacuo.* With a "Holtz's" machine, which will give 11-inch sparks in the air, four well-marked different kinds of discharge have been obtained *in the air;* one of which, the author thinks, will explain the curious and rare phenomenon known as "ball lightning." In the experiments hereafter referred to, the condensers were in all cases attached to the "Holtz's" machine. The first discharge is the long 11-inch zigzag spark or lightning-flash; the second is the well-known "brush," which is best obtained by connecting the negative pole of the "Holtz's" machine to the earth; the third kind of discharge is a hissing red flame, $\frac{1}{2}$ inch in length, playing about the negative pole, the positive pole being scarcely luminous at all, and if luminous, at one or two points only; the fourth or most remarkable phenomenon is best obtained in the following manner (I should here remark that the brass balls on each of the poles are about an inch in diameter):—Tie to the negative pole a small thin strip or filament of wood three inches in length, and bent so as to project on each side of the negative pole, and a little beyond it towards the positive. On rotating the machine, two bright spots are seen upon the positive pole. If the positive pole be made to rotate upon its axis, the luminous spots do not rotate with it; if, however, the *negative pole,* with its filament of wood, be rotated, the spots on the *positive pole obey it,* and rotate also. The insertion of a non-conductor, such as a strip of glass, in front of the projecting wooden end, obliterates the luminous spot on the positive pole. When the author first discovered this, he, seeing apparently pieces of dirt on the positive pole, wiped it clean with a silk handkerchief, but there they remained in spite of all wiping; he then examined the negative pole, and discovered a minute speck of dirt corresponding to the luminous spots on the positive pole. When the filament of wood is removed from the negative pole there is sometimes a luminosity or glow over a large portion of the surface of the positive ball. If in this state three or four little pieces of wax, or even a drop or two of water, be placed upon the negative pole, corresponding non-luminous spots will be found upon the positive pole, which rotate with the former, but do not with the latter. It is therefore evident that there are lines of force existing between the two poles, and by these means one is able to telegraph *from* the negative *to* the positive pole to a distance of 8 inches through the air, without any other conductor than that which the electrical machine has constructed for itself across the non-conducting gas. The foregoing seems to the author to give a possible explanation of "ball-lightning;" if it be possible for there to be a negatively electrified cloud sufficiently charged to produce a flash from the earth to the cloud, a point in the cloud would correspond to the wood projection on the negative conductor; if such a cloud exist, a luminous spot would be seen moving about the surface of the earth, corresponding to the moving point of cloud over it, and thus present phenomena similar to those described by the privileged few who have witnessed this extraordinary natural phenomenon. The following experiment shows that, prior to the passage of the electric spark, a channel is prepared for this spark to pass. The positive and negative balls of the machine were separated to a distance of 6 or 7 inches, and a common candle-flame was placed midway between them. On rotating the machine, the flame was drawn out on each side just prior to the passage of the spark. Sometimes it extended to a width of 5 or 6 inches; this took place every time the spark passed. It is well known that the duration of this spark is less than the $\frac{1}{100000}$ part of a second; the flame occupied the $\frac{1}{8}$ or $\frac{1}{10}$ part of a second in flying out to make the conducting channel through which the discharge went. The author has been informed more than once by captains of vessels, that when men have been struck by lightning a burn has been left upon the skin of the same shape as the object from which the discharge flew. In one instance he was informed that some brass numbers, attached to the rigging from which the discharge passed to the sailor, were imprinted upon his skin. It is now seen that this is perfectly possible if the discharge be a negative one, that is, if the man be + to the brass number.

Ethnological Society, January 10.—Prof. Huxley, President, in the chair.—Mr. Francis Hewitt was announced as a new member.—A collection of stone implements from Queen Charlotte and Vancouver Islands was exhibited by Dr. Hooker, C.B., and some artificially distorted skulls from Vancouver Island were exhibited by Col. A. Lane Fox.—A paper was read, "On the Prehistoric Monuments in Brittany," by Lieut. S. P. Oliver, R.A., illustrated by a large collection of drawings and plans. The author first described the alignments at Carnac, which are arranged in three distinct groups—those of Menec, Kervario, and Kerlescant. At Menec there are eleven lines of stones with a circle at the south-west; at Kervario there are ten convergent lines; and at Kerlescant thirteen lines, with an enclosure of horse-shoe form. The stone avenues of Erdeven, St. Barbe, St. Pierre, and Plouhinec, were also noticed among the antiquities of the Morbihan; and attention was then directed to the alignment of Crozon, in the neighbouring Department of Finisterre. From the rude character of the stones in all these avenues and circles as compared with those in the neighbouring dolmens and menhirs, the author believes that the megalithic remains are of two distinct classes, differing considerably in date, the alignments and circles of amorpholiths being referable to a much earlier race than the dolmen-builders. Many of the tumuli of Brittany were then described, and attention directed to the archaic sculpturing upon some of the stones, and to the celts which have been found within the tumuli. Of these celts a large proportion are formed of the rare mineral *fibrolite*. The discussion upon this paper was sustained by Sir H. Dryden, Capt. Godwin-Austen, the Rev. H. Winwood, and Messrs. A. W. Franks, Hyde Clark, and Edgar Layard.—Some notes were read on a Cairn near Cefn, St. Asaph, by the Rev. D. R. Thomas, M.A., and T. McK. Hughes, M.A. The authors described two chambered tombs within the area of a large cairn which had long been removed. One of these cists was brought to light by excavations, which were undertaken in consequence of a visit to the spot by a party from the British Association after the Liverpool meeting.

NORWICH

Norfolk and Norwich Naturalists' Society, December 20.—A box of very beautiful and rare fen moths, presented by the Hon. T. de Grey to the Museum, was exhibited.—Mr. Stevenson read a paper on "The Abundance of Little Gulls on the Norfolk Coast in the Winter of 1869-70." This bird has hitherto been considered an occasional straggler on the Norfolk coast, but during the month of February last an unprecedented number appeared. It is probable that over sixty specimens were killed in this county; of these the great majority were adult males. These birds have recently been discovered to breed in considerable numbers in Lake Ladoga, further to the north and west of which it is not at present known to breed. Mr. Stevenson presumes that the stragglers, mostly young birds, which in autumn and winter appear on the coast of Great Britain, form part of that colony, which, migrating in a westerly rather than in a southerly direction, pass from the Baltic into the North Sea. The adult birds rarely approach the shore, but, from the sudden and irresistible force of the gale which visited us in February last, they were, doubtless, compelled to seek the shelter of our bays and estuaries.—Mr. Barrett stated that, since he read his paper on "The Coast Insects found near Brandon," at the last meeting, he had received some valuable evidence confirmatory of the views he then expressed. The Hon. T. de Grey informed him that he had taken *Agrestes cinerea* and *Gelechia vitella*, both of them rare sandhill insects, at Brandon, and *Gelechia marmorea* as far away as Tottington, on the Merton estate. Other species had been taken by the Rev. H. S. Mariott, of Wickham Market, and the Rev. H. Williams, of Croxton.—Mr. Geldart stated that *Phleum arenarium*, an essentially sea-side grass, was to be found growing on the sandy warrens about Brandon.

DUBLIN

Royal Geological Society, January 11.—"On the Geological age of the Ballycastle Coal-field, and its relation to the carboniferous rocks of the West of Scotland, by Mr. E. Hull, F.R.S." The object of the paper was to prove that the coal-field of Ballycastle, Co. Antrim, was referable to the type of the lower coal-field of Scotland, and consequently of the age of the Lower Carboniferous series; in other words, of the mountain limestone. The Carboniferous series of Ballycastle which had been described in 1829 by Sir R. Griffith, F.R.S.,* was shown to consist of three divisions in descending order. 1. *The Upper*, consisting of massive sandstones, and shales with beds of coal, black band and clay band ironstones, &c. (*Lingula squamiformis*). 2. *The Middle*, consisting of a thin bed of limestone lying between shales with carboniferous limestone genera and species of shells, crinoids, and corals. 3. *The Lower*, consisting of massive reddish grits, and conglomerate with thin beds of shale. The author showed that the carboniferous limestone of Ireland undergoes, in its extension northward, changes similar to those of the same formation in Britain, when traced from Derbyshire into Northumberland and Scotland. The calcareous element thins away, and is replaced by sedimentary strata of sandstone, shale, &c., with approximately terrestrial conditions, productive of coal and ironstone. It was thus that in the case of the Glasgow coal-field, the limestone of Derbyshire, several thousand feet in thickness, was represented by only thin bands of earthy limestone, interstratified with a thick series of grits, shales, &c., with ironstone and coal. In a similar manner the Ballycastle coal-field, with only a few feet of limestone, shown in the cliffs of the bay, was the representative of the carboniferous limestone of the centre of Ireland, nearly 3,000 feet in thickness. Mr. Hull regarded the lower division (No. 3) of the Ballycastle beds (as above described) as undoubtedly the representative of the "calciferous sandstone series" of the Geological Survey, which lies at the base of the carboniferous rock of the West of Scotland, and that the middle and upper division (Nos. 2 and 1) corresponds to the carboniferous limestone series, or lower coal-field of that country. As regards the palæontological evidence, it was in favour of this view, as far as it had been studied. Out of thirty-three species observed in the limestone band of Ballycastle Bay, 50 per cent. had been described in the Lower Carboniferous rocks of the West of Scotland,† and one of the uppermost seams of coal, lying above the limestone, had yielded *Lingula squamiformis*, a form characteristic of the limestone series in the North of England, Scotland, and Ireland. Mr. W. H. Baily, F.G.S., concurred in the view of the age of these beds on palæontological grounds. The author concluded by pointing out several features of similarity between the Ballycastle beds and the lower coal series of the West of Scotland, such as the occurrence of several beds of "black band" ironstone; the hydraulic and earthy character of the limestone of Ballycastle Bay, exactly resembling the "Arden" and "Cowglen" bands of Glasgow. Some uncertainty still remained whether there were any beds in the Ballycastle district as high in the Geological Series as the millstone grit, a true coal measure, but until more light could be brought to bear on this question by further exploration, and a complete investigation by Government surveyors, the author meanwhile regarded the whole series as Lower Carboniferous.

MONTREAL

Natural History Society, Nov. 28.—Dr. Dawson, president, in the chair. A paper was read upon the Canadian phosphates of lime in their application to agriculture, by Mr. Gordon Broome, F.G.S., calling special attention to the valuable apatite deposits of the Rideau district. The author gave a large amount of valuable information upon the manufacture of "superphos-

* Report on the Coal Districts of Tyrone and Antrim, addressed to the Royal Dublin Society, 1829

† Trans. Geol. Soc., Glasgow.

phates," noticing the good work being done at Brockville in this particular branch of industry, and proving that large areas of land now wholly or partially exhausted, in various portions of Lower Canada, might still have been yielding large returns of wheat and other cereals, had they been farmed upon a rational system of agriculture, coupled with the judicious employment of phosphatic and other fertilisers. We quote from the concluding words of this comprehensive essay: "He made especial reference to the comparative dormant state of this, and other equally obvious sources of industry in Canada, arising from a great deficiency in a most important division of our national education, and that nothing save a liberal augmentation of the ordinary courses of instruction in modern subjects can ever dispel the immense existing clouds of ignorance and prejudice. It is, therefore, sincerely to be hoped that the very able remarks recently made by Principal Dawson upon this question may have their desired effect, and that Canada may speedily obtain a share in the improvements that have of late almost revolutionised the systems of educations in the universities of the mother country." Dr. Hunt, Vice-President of the Association, then referred in a feeling manner to the loss sustained by science in Canada, in the death of Mr. Hartley, of the Geological Survey, who, though only twenty-three years of age, was one of the most promising young men in the country.

VIENNA

I. R. Geological Institute, December 20.—M. Fr. v. Hauer stated that the Institute had happily come into possession of the only known specimen of Psephophorus polygonus from Neudörfl in Lower Austria, which had been described after a drawing more than twenty years old by Herm. von Meyer, and had been designated by him one of the most interesting fossil remains of a vertebrate animal ever found in Austria. It consists of a plate of epidermal scales nearly two hundred in number, and perfectly irregular in size and form. H. v. Meyer thought it to belong to an animal of the family of the Dasypodidæ, whilst Prof. Müller compared an analogous plate found in the Zeuglodon beds of North America with the plate of Dermatochelys.—M. F. v. Vivenot read a memoir on the microscopical examination of the syenite of Blansko in Moravia, in which, besides the minerals which are distinguishable with the naked eye, as oligoclase, quartz, amphibole, biotite, titanite, and magnetite, he discovered also orthoclase, epidote, and apatite.—M. E. Tietze exhibited specimens of cornubianite from Servia, which perfectly resembled the cornubianite of Cornwall, and like it were found in a stratum interposed between granite and argillaceous schist.—M. Posepny communicated his observations on the beds of rock-salt in Transylvania.

PHYSICAL LABORATORIES

IT is well known that chemistry can be taught far better by a laboratory in which the student performs the various experiments, than by any system of lectures. Now, although for many years physicists have been in the habit of instructing their special students and assistants in this way, yet it is only recently that the same plan has been tried with large classes in physics. One of the first institutions to attempt this method, in America at least, was the Massachusetts Institute of Technology in Boston; and as I find many colleges here establishing physical laboratories, I trust that our experience may prove of some interest. The great difficulty is to enable twenty or thirty students to perform the same experiment without duplicating the apparatus, and to avoid the danger of injury to delicate instruments. Our plan is this:—Two large rooms (one nearly a hundred feet in length) are fitted up with tables, supplied with gas and water, somewhat like a chemical laboratory. On each is placed the apparatus prepared for a single experiment, which always remains in this place, thus avoiding the danger of breaking it in moving. A full written description is also given of each experiment, pointing out the proper precautions to avoid error or breakage. Near the door is an indicator or board containing the names of the experiments, and opposite each is placed a card bearing the name of the student. When the class enters the laboratory, they go to the indicator, and each member notices what experiment is opposite his name; he then goes to the proper table, reads the description, and performs it. He next reports his results to the instructor in charge, and if they are correct, his card is moved to some unoccupied place, and he proceeds as before. Care is taken that the number of experiments shall exceed that of students, and there is therefore no delay. The instructor in the mean time is enabled to pass from student to student and to see that no errors are committed. As quantitative work is far more valuable than qualitative, most of our experiments are of the former kind, and the student learns to measure physical constants and to verify laws numerically. For example, in one experiment a steel bar is supported on knife edges, and a weight is applied at the centre. The flexure is then measured by a micrometer screw, the exact point of contact being determined by including the screw and bar in the circuit of a battery and galvanometer. After making a number of experiments with various weights, the student constructs a curve in which ordinates represent deflection, and abscissæ weights applied. The law of elasticity shows that this curve should be a straight line, and the close agreement is convincing proof to the student of its correctness. In the same way the law of the conjugate foci of lenses is tested, and the observed curve compared with that deduced from theory. Some experiments are introduced to accustom the student to general methods of research, such as the computation of probable error by least squares, various forms of interpolation, &c. The graphical method is largely used, as it at the same time enables the student to take in all his observations at one glance, while the instructor can constantly tell how carefully the work has been done. For the microscope a few objects are selected to show certain general methods of using this instrument, as one requiring a diaphragm, a second oblique illumination, and so on. Again, the student views by polarised light such objects as unannealed glass, crystals, designs in selenite, and studies the effects produced by various agencies. By thus handling the instruments he acquires a facility in using them and comprehension of their construction which he could never obtain from lectures. The excellence of the work done by many of the students led to the hope that valuable results might be attained by assigning to different students the experiments in a research, taking care that each should be repeated several times by different individuals. These results, if concordant, would be much more conclusive than those obtained by a single experimenter, since they would be free from all personal bias. In this way some interesting results have been attained on the foci of lenses placed obliquely, the flow of air through straight and curved tubes, and other similar subjects. Photometry and electrical measurement seem especially suited to this purpose, and the application of the latter subject to submarine cables would be both interesting and instructive to the student. During the winter time of 1869 and 1870 about sixty students worked in one laboratory, so that the experiment was tried on a sufficiently large scale to enable us to speak with confidence of its success. We found the system described above worked well, the students were interested in the subject, and obtained results of considerable accuracy. The loss by breakage was exceedingly small, and the current expenses insignificant compared with a chemical laboratory, since there is but little consumption of the materials employed.

There are now in America at least four similar laboratories either in operation or preparation, and the chances are that in a few years this number will be greatly increased. The value of a knowledge of physical manipulation is becoming daily better appreciated, and it is evident that instruction of this kind can be properly given only in a physical laboratory.

EDWARD C. PICKERING

SCIENCE TEACHING IN PRIVATE SCHOOLS

A WRITER of the early part of last century defined a philosopher as one "whose trade was to do nothing, and to speculate upon everything." While philosophers were so lightly esteemed, it is no matter of surprise that philosophy was little cared for as a part of education. But such a definition as the above would not now be generally accepted even by the unscientific public. All are beginning to see that it is to Science they are indebted for so many of the comforts and advantages of civilisation, yet to the many is Science a mystery and closed book. And one great cause of this we believe to be, because it is not taught in our schools.

We purpose, in the present article, to speak only of private schools. If a visitation were to be made of such schools in England, we venture to say that very few, comparatively, would be found, in which Science, in any of its branches, is made a subject of regular education. The boys of most schools would be classed by the masters under three heads, classical boys, mathematical boys, and good-for-nothing boys. This last class exists mainly because the proper food for them has not been provided, they are allowed to starve for lack of it, and grow up as men with stunted and impoverished intellects; they have not been educated, the powers of their minds have not been drawn out by the fit means, and they pass through the world as animated failures.

Let Science work side by side with Classics and Mathematics—not usurp their places—in the work of education, and the good-for-nothing class will be very sensibly diminished, if indeed it be not entirely done away with. But how is this to be done? In the first place, gradually; in the second place, zealously; in the third place, thoroughly. Gradually, because it is a new thing, and a large proportion of our private schoolmasters have had no regular training in science themselves. Zealously, because if a teacher be not himself interested in what he teaches, he can have no assurance of success, and no encouragement from his pupils. Thoroughly, because a thing worth doing at all is worth doing well.

This is the spirit in which the work must be done. but what are the special means? Are boys to read about Science merely, or are they to touch and handle Science for themselves? It is doubtless a good thing to read about the truths of Science and their experimental illustration; it is a better thing to see those truths illustrated and proved by another; but it is by far the best thing to experiment upon and prove the truths by one's self. There is nothing that comes home so much to a boy's mind as an experimental proof. He may read of the dual character of electricity, and may get some vague ideas on the subject; as soon, however, as he takes two sticks of sealing-wax, suspends one, rubs both, and brings one near to the other, he, as it were, discovers for himself that the same bodies electrified by the same means repel one another, and on experimenting with glass and sealing-wax sticks he learns something of attraction, and is naturally led on from experiment to experiment until the powers of his mind become quite drawn out, or educated in the pleasurable pursuit of the subject. In the Science-teaching of boys, then, practical demonstrations must play an important part. Let reading, hearing lectures, and attending classes, and individual experimentation, be the working tools. A lecture of itself is but a poor tool, it produces an effect for the time, but in many cases no very permanent good. A lecturer must also be a teacher out of lecture hours.

As a commencement of Science-teaching in schools we commend the following plan to the notice of Science-teachers. Let one or two evenings in the week be set apart for lectures on some branch of Science, Experimental Physics, Botany, or Geology. Each lecture to last *not more* than an hour, and to be experimentally illustrated in the way best suited to the subject, always bearing in mind that the simplest experiments, or those most easily imitated by the pupils, are the best. Let the pupils be encouraged to take notes, and let the lecturer sum up in a concise form at the end of the lecture the main points established, which may be written in the form of memoranda on a black board and copied by the pupils. A day or two after the lecture let him hold a conversational class, the attendance optional. He will then briefly run over the matter of the last lecture, find out by questioning what points are not thoroughly understood, re-explain or even re-experiment, and endeavour to leave each mind with a perfect understanding of fundamentals. On a third evening let him give a series of simple—not needlessly puzzling—examination questions, and look over each boy's answers with himself alone, if possible, in order to give an opportunity for a yet more thorough explanation of any difficult point suited to the individual capacity of each. Instead of a string of questions, a subject for an essay in connection with the lectures might occasionally be given. Private reading of text-books should always be encouraged.

Now, as to the results of a system of this kind, taking such a subject as Experimental Physics, it will be found that the lectures are always looked forward to with no ordinary pleasure, and are listened to with no ordinary attention. At the conversational classes the way in which such subjects teach boys to think is often clearly seen; they ask most puzzling questions, yet natural ones, and in many cases seek to go far deeper into the subject than the lecturer had at first any idea of leading them. This general interest incites them to read and perform such simple experiments for themselves as are within their power.

Generally speaking it is not the high classical or even the mathematical boys that have excelled in Science learning, but precisely those who before occupied no prominent place in the school, had no special gift for classics or mathematics, and were considered, more or less, good-for-nothings. And here it is important to remember that a person may have a mathematical mind without being a mathematician.

While such subjects as Chemistry and Physics claim, perhaps, the highest position as a means of scientific education, it is important to vary the programme as much as possible without treating any superficially. Thus Astronomy, Geology, Physiology, and Botany have strong claims. It is certainly most deplorable to think that even now in many of our private schools the pupils are being tacitly taught that the world was made in six days, and that man is but some 6,000 years old. They might as well learn that there are but four elements—earth, air, fire, and water. We look with confidence for better things in the future.

COHN'S CONTRIBUTIONS TO THE BIOLOGY OF PLANTS

Beiträge zur Biologie der Pflanzen. Herausgegeben von Dr. Ferdinand Cohn. Erster Heft. Mit sechs zum theil farbigen Tafeln. (Breslau, 1870. London: Williams and Norgate.)

THIS is the first part of a new periodical established primarily for the publication of the results of the observations made at the Botanico-Physiological Institute at Breslau. The part contains five papers on different microscopic algæ and fungi, and their pathological effects. In subsequent numbers it is intended to give priority to botanical observations which relate to biological questions, or which are more or less connected with practical natural science, medicine, agriculture, &c. It is hoped that the publication may fill the place formerly occupied by Karsten's "Botanische Untersuchungen."

We propose here to give a short account of the contents of the present number. The first paper (by Dr. J. Schroeter) is on the parasites of the genus *Synchytrium*. The *Synchytria* form a small group of parasitic cryptogams, remarkable for their peculiar mode of development and the absence of any mycelium. They produce small swellings, or "galls," on the plants in which they occur, but in comparison with other parasites cause little injury or distortion. The genus was established by De Bary and Woronin in 1863 for the reception of the plant now known as *Synchytrium Taraxaci*. Several other species have since been discovered, the number of those described by Dr. Schroeter in the present paper amounting to eleven. The plants were divided by Woronin into two groups. In the first the protoplasm of the cells is white, and the zoospores pass at once into the condition of resting spores. In the second group the protoplasm is reddish, and the zoospores, attaching themselves to living plants, produce spherical masses of zoosporangia until the close of the vegetative period, when they produce resting spores. Dr. Schroeter proposes three groups, which he calls *Eusynchytrium*, *Chrysochytrium*, and *Leucochytrium*. The first corresponds to Woronin's second group, the second to Woronin's first group, and the third comprehends certain *Synchytria* which agree with those of Woronin's first group except in having white protoplasm. Dr. Schrœter describes the species with great care, and in considerable detail, and the descriptions are for the most part illustrated by excellent plates. He considers the genus to be one of wide distribution. With regard to its systematic position, there has never been any doubt that *Synchytrium* belongs to the *Chytridiaceæ*, but whether the latter are fungi or algæ is not so well settled. The conclusion at which the author has arrived is that they should be placed as a distinct family amongst those *Palmellaceæ* which produce zoospores, being nearly related to *Hydrocytium*, *Codiolum*, and their allied genera.

In the second paper ("Ueber die Fäule der Cactusstämme") MM. Lebert and Cohn describe a new species of *Peronospora*, which was most destructive to a collection of cactuses, affecting particularly *Cereus giganteus* and *Melocactus nigrotomentosus*. The epidermis of the cactus was not materially altered, but the cellular tissue beneath became entirely rotten, the decay beginning with the inter-cellular substance: so that the parenchymatous cells were easily separable from one another. The contents of these cells became brown, and the cell-membrane almost entirely dissolved, the cactus thus exhibiting an internal state of decay similar to that seen in diseased potatoes. The fungus is closely allied to the potato blight, *Peronospora infestans*, which it resembles in having the hyphæ only slightly ramified, not dichotomous and therefore producing but few conidia, as well as in its delicate mycelium (which has no suckers) and in the swellings underneath the large, beaked conidia. The authors suspect that the fungus must have been imported with the cactuses from America.

The third paper, by Dr. Cohn, is entitled "Ueber eine neue Pilzkrankheit der Erdraupen," and contains a detailed account of a fungoid disease affecting the caterpillars of *Agrotis segetum*. The skin turns black, a coal-black pigment appears in the blood, and the caterpillar becomes a wrinkled and brittle mummy. Upon examining the interior the whole cavity of the body, except the intestinal canal, is full of a black tinder-like substance, consisting of very large, dark brown spores, which are globular, but sometimes wrinkled at the surface, so as to present a crenate outline under the microscope. Contemporaneously with the colouring of the blood, cylindrical or curved tubes (*Schläuche*) are seen, which become divided by septa, and form rows of cells which separate from one another and appear in the blood as free globular or oval cells. These Dr. Cohn calls *gonidia*. These gonidia germinate shortly before the death of the grub, and produce a mycelium which displaces the inner organs, except the intestinal canal and the tracheæ, and fills the hollow of the body. This mycelium produces partly new gonidia and partly the dark spores already mentioned. The latter are probably resting-spores, as it seems from Dr. Cohn's observations that they do not germinate until the spring. The fungus (to which the author gives the name *Tarichium*) appears to be generically the same as Fresenius's *Entomophthora*, and to be closely allied to *Empusa*. Dr. Cohn thinks it not improbable that *Empusa* and *Tarichium* are stages of development of the same fungus; that *Empusa* may be the conidial form of a fungus of which *Tarichium* represents the teleutospores. If so, *Empusa* bears the same relation to *Tarichium* as *Oïdium* does to *Erysiphe*, *Uredo* to *Puccinia*, and (perhaps) as the *epi*phytal conidia of *Peronospora* to the *endo*phytal oospores.

We have but little space to notice the two remaining papers. One is by Dr. Schroeter, and relates to a disease affecting *Pandanus*, which was observed many years ago by Sinnig, the Inspector of the Botanic Garden at Poppelsdorf, and which has since been investigated by Bouché, at Berlin. In the spring of the present year it attacked a splendid specimen of *Pandanus odoratissimus*, Jacq., in the gardens at Breslau; the branches decayed, and it was found necessary to cut off the crowns, afterwards the branches themselves, and eventually the greater part of the entire plant, leaving only a portion of the stem and a single branch. A strict investigation afforded no ground for supposing that the disease had been produced by cold, drip, or other causes which would suggest themselves to cultivators, but a fungus was discovered identical with one described by Leveillé as long ago as 1845, which occurred in the Botanic Garden at Paris upon *Pandanus*, and which he called *Melanconium Pandani* (Ann. d. Sciences Nat. ser. iii. t. 3, p. 66). The *Melanconium* in the present case was accompanied by a *Nectria*, which Dr. Schroeter considers to be the *Nectria Pandani*, Tul., and conidia were also observed, the mycelia of which exhibited the forms of *Tubercularia*, *Stilbum*, and *Verticillium* or *Penicillium*. The author considers it extremely probable that the *Melanconium*, the *Nectria*, and the conidia are produced from the same mycelium, the fungus thus exhibiting the following forms of fruit:—1. Grey-green conidia (*i.e.* the *Melanconium* fructification). 2. Colourless conidia, the supports of which assume three different forms, viz. (*a*) *Tubercularia*, (*b*) *Stilbum*, (*c*) the form of such moulds as *Verticillium* or *Penicillium*. 3. Spores in asci formed in orange-red perithecia seated on a *Stroma*.

Dr. Schroeter concludes that there can hardly be a doubt that the fungus is the direct cause of the progress and of the destructive operation of the malady, and that it is probable, though not so certain, that the spores germinate in the healthy stem, and actually produce the disease.

The last paper contains a description by Dr. Cohn of a plant which he has discovered in well-water at Breslau, and to which he has given the name of *Crenothrix polyspora.* The genus is new and is closely allied to *Chamæsiphon*, being intermediate between that and *Lyngyba.* It would take too much space to describe the plant at length, for the particulars of which we must refer to the paper, in which will be found, moreover, some interesting observations upon the microscopical analysis of well-water in general. The *Crenothrix* was first noticed in water from a well at Breslau, in a part of the town notorious for the prevalence of typhus. It has been found also in other wells of bad reputation, but whether it has any injurious effect upon the health of the dwellers in the neighbourhood of the wells in question Dr. Cohn cannot venture to say.

It will be seen, from what has been said, that the periodical under notice is well deserving the attention of botanists and physiologists, and from the reputation of its editor there is every reason to hope that the scientific interest of future numbers may equal that of the present one. F. CURREY

OUR BOOK SHELF

Matheran Hill, its People, Plants, and Animals. By J. Y. Smith, M.D. (Edinburgh: Maclachlan and Stewart.)

THIS is perhaps the first attempt that has been made to give a comprehensive account of the natural history of any particular spot in our East Indian possessions, and we welcome this little book as a sample of what may be accomplished by residents there in the midst of their official occupations. The undertaking is worthy of all praise, and, as far as it goes, it is a valuable contribution to the ethnology and natural history of India, and will no doubt be the groundwork for further research, and lead to other similar works.

The hill of Matheran is within twenty miles of the coast of Bombay, it is basaltic, and rises in the centre of a vast plain to the height of about 2,600 feet, it is precipitous on all sides, flat on the summit, which has an area of about five square miles, and is clothed with luxuriant vegetation; it is, in short, one of the most charming spots in India. In less than three hours one can be transported from the heat, dust, and noisy traffic of Bombay to what appears to be another world, where the body is refreshed and invigorated by the pure mountain air, and the spirit soothed by the beauty of verdant foliage, the cheerful music of feathered songsters, scenery grand and picturesque, and the general repose of nature. To the naturalist Matheran opens a grand volume to him, the little plateau has an air of enchantment, and he has spread out before him in the most attractive form objects which will supply him for even years with delightful and instructive occupation without the toil and exposure of long journeys. To such Dr. Smith's account of the more prominent objects to be met with will therefore be a valuable boon, and, indeed, to all lovers of nature who may visit the place. Let the home botanist imagine himself in a pretty little cottage on Matheran, with no less than seventy-five flowering trees and shrubs within a mile of his residence; not to mention climbing plants, creepers, herbs, parasites, and ferns in abundance. As the author is now returning to the East, we hope he will have opportunities of extending his interesting observations, especially on the birds and insects. To the geologist, Matheran is an object of interesting study; he will there see that curious rock called laterite or iron stone clay, the nature of which has been so much disputed, capping the great basaltic formation (to use a homely phrase) like the sugar on a Christmas cake, and if he extends his observations to the north and south, he will find the same capping on other hills, thirty to sixty miles distant, while no trace of it exists in the interval between. To what bold speculations does this fact give rise? Did this laterite once cover the whole country as with a mantle, and are present appearances due to a vast denudation of hard trappean rock 2,000 to 3,000 feet deep?

We are glad to find natural history included among the subjects for Indian Civil Service examinations, for hitherto this class of Europeans in India have contributed comparatively little to our knowledge of that wonderful land "where all, save the spirit of man, is divine."

A Voyage Round the World. By the Marquis de Beauvoir. 2 vols. (Murray, 1870.)

THIS is the gossiping journal of a young companion of the Duc de Penthièvre, son of the Prince de Joinville, often amusing and spirited, but of little permanent value. We have the usual exaggerations of a novice in the tropics. At Batavia he speaks of "this torrid temperature of 104° in the shade," a degree of heat never experienced by the present writer during many years' residence in those regions. The author's scientific attainments may be estimated by his account of his visit to the Melbourne Museum, when he makes Prof. MacCoy speak in this fashion:—"The stratum of alluvial soil covering the crust of primitive rocks, which formed round the earth while it was still in a liquid and incandescent state, possesses the same specific type of animal life that characterises the ancient strata of Wales, Sweden, and North America. Then come soils identical with those of these countries, schist and fossil rocks; thus Canada, Scotland, and the province of Victoria have all passed through the same form of existence at this remote period." The countries described are Australia, Java, Siam, and Canton, and the whole journey occupied about six months.

A. R. W.

The Student and Intellectual Observer. A Quarterly Journal of Science, Literature, and Art. Vol. 5. (London: Groombridge and Sons.)

THE volume now before us is in every way worthy of the reputation of its predecessors. Four papers on poison are contributed by Mr. F. S. Barff, and Dr. Carpenter contributes two interesting papers on the "Deep Sea," the first on its physical, and the second on its biological condition. The author's experience in these matters, owing to his connection with recent explorations, make the papers the more interesting, because they are the words of an actual and accurate observer. Dr. Collingwood also gives a very readable paper on a kindred subject, "The Sargasso Sea and its Inhabitants," in which the Sargassum or Gulf-weed comes in for a good share of attention, being, as it is, the home of multitudes of Polyzoa, Polyps, Crustacea, Molluscs, and similar creatures. Mr. Shirley Hibberd talks about Cycads under the very misleading title of "Sago Palms." At one time the Sago of commerce was supposed to be the produce of the Cycads, but now we know that the bulk of this useful article is yielded by two or more species of *Sagus*, true palms; it is, to say the least, advisable that an old term proved to have been wrongly given, should not be perpetuated. The author, however, does attempt to qualify its use in the following sentence:—"By 'Sago Palms' is to be understood the great group of gymnospermous plants, of which the Cycads and their allies are representatives, a group possessing powerful morphological relations, and, of course, a correspondence within certain limits in all their biological characteristics." The volume contains many other interesting papers in various branches of science, and we conclude this short notice by wishing well to an old-established monthly in its new quarterly form.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

The Isolation of St. Michael's Mount

MR. PENGELLY, in a letter addressed to you, and printed in your journal of Jan. 12, 1871, complains of my having ascribed to him a belief in the extreme antiquity of the Cornish language which he does not hold now, and which he did not hold at the time when he delivered his first lecture "On the Isolation of St. Michael's Mount," at the meeting of the British Association at Birmingham in 1865. He declines to be responsible for any notices or report of his lecture that I may have seen in some newspaper or journal.

All I can say in my defence is that even while the meeting at Birmingham lasted, I received not only newspaper reports, but letters from friends who had heard the lecture, and who asked me in great dismay whether it was possible that a Cornish name, such as *Cara clowse in cowse*, meaning "the hoar rock in the wood," could have existed in so called prehistoric times.

The question discussed at the meeting, so far as I could understand it from letters and the official short report in the Transactions of the British Association, was this, whether St. Michael's Mount was severed by encroachment or subsidence. Those who held the former view required 20,000 years, those who held the latter were satisfied with a smaller number of years, though I could not find out exactly what that number was. Both parties maintained that Cornish must have been spoken in Cornwall before the severance of the Mount took place, because only before that severance could the Mount have been called *Cara clowse in cowse*, "the hoar rock in the wood."

What I wanted to show was simply this, that neither party could properly avail itself of the linguistic argument, whether for positive or negative purposes. If the Mount was severed 20,000 years ago, it would not follow from the name *Cara clowse in cowse*, "the hoar rock in the wood," that Cornish was spoken at that distant time; nor would it in the least follow from that name that the severance could not have taken place until Cornwall was occupied by Celtic speaking tribes. The linguistic and geological evidence can in no wise be brought to bear upon each other.

If I said that "Mr. Pengelly has somewhat modified his former opinion," all I meant was that in his second paper he himself seems much less inclined to trust to the linguistic and legendary evidence. But if in his letter to you he says that the point of his argument was that the hypothesis of insulation by encroachment without subsidence could not be admitted because it led to an untenable philological conclusion, this shows that the old leaven is still at work. If the facts which I collected in my essay on the Insulation of St. Michael's Mount are right, that hypothesis would lead to no untenable philological conclusion whatever, for the simple reason that the name *Cara clowse in cowse*, or "hoar rock in the wood," referred originally to Mont St. Michel, in Normandy, if not to Mons Garganur in Apulia, and does not occur in Cornwall before the 16th, or possibly the 15th century of our era.

If I have in any way misrepresented the exact geological reasoning of Mr. Pengelly, all I can do is to plead the ignorance of a layman, and to ask his forgiveness.

Oxford, Jan. 23 MAX MÜLLER

Earth-Currents

IN Mr. W. H. Preece's communication concerning the earth-currents which occurred on the 24th and 25th of last October in England, published in your issue of the 3rd of November, just come to hand, he says: "This is only a sample of what occurred simultaneously all over England, and probably the globe."

The following few extracts from the Log of the Madras-Bombay Lines show what was taking place out here:—

"Oct. 24, 22 hours, working Bellary with great difficulty. Severe lightning taps on instrument every now and then." "Oct. 25, 8 hours, strong earth-currents at times.—17 hours to 17·45 hours, very strong earth-currents.—22 hours, working Bombay with frequent stoppages, owing to strong earth-currents and failure of signals." Such is the character of the log throughout the 24th and 25th of October.

The direction of the Madras-Bombay Lines (nearly east and west) would account for the fact of the earth-currents being so strongly pronounced in them.

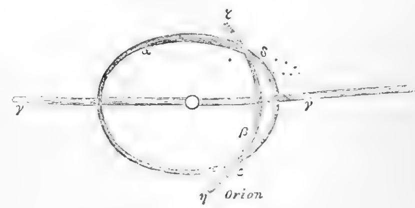
R. S. BROUGH,
Assistant Superintendent of Government Telegraphs in India

Lunar Bows

A REMARKABLE phenomenon was visible at Liverpool from 7.30 to 7.45 P.M., on Wednesday, 4th inst.

The moon was nearly full at an altitude of 45° or 50°, just above Orion, the sky was covered with a slight mist sufficiently dense to obscure all stars except those of the first magnitude, though here and there some of the lesser were visible.

There appeared three lunar bows or halos—$\alpha\,\beta\,\gamma$ in sketch. α was nearly but not quite a perfect circle, having a slight tendency to an oval; it was complete. β was an excentric cutting α at points

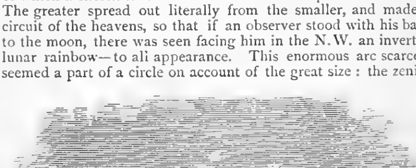


δ and ϵ, and was incomplete, only having about 90° of its circle visible, being lost to sight at ζ and η. γ had the zenith for its centre, cutting the moon; its circle was complete, intenser in the western sky and dimmer at its nearer proximity to the moon, thus forming a belt round the whole heavens, cutting off the upper portion.

I venture to consider these interesting sights worthy of a space in NATURE, as they took up so large a space in the heavens.

Liverpool F. J. J.

ON Wednesday evening, January 4th, while the frost still lasted, there appeared, about 7.25 P.M., two brilliant halos, of which a sketch is forwarded. Neither was perfect in outline. The greater spread out literally from the smaller, and made a circuit of the heavens, so that if an observer stood with his back to the moon, there was seen facing him in the N.W. an inverted lunar rainbow—to all appearance. This enormous arc scarcely seemed a part of a circle on account of the great size: the zenith



was about its centre. After meeting the smaller halo it was scarcely visible, but it produced would have passed through the moon's disc. At the point of intersection towards the east, a faint paraselene appeared.

When this singular sight was seen, there was but little cloud in the sky. The blue was, however, rather turbid. The prismatic colours were tolerably distinct in the inner arc. The diameter of the large circle was about 90°. There has been a considerable amount of rain and snow since the appearance.

SAMUEL BARBER

Aigburth, Liverpool, Jan. 9

Yellow

In the paper on colour read by Mr. Strutt before the British Association (Nature, Jan. 19) two things are stated as requiring explanation (p. 238), both of which, it seems to me, are explained by one of the results furnished by such experiments as his own.

The first is the difficulty usually found in recognising the demonstrated fact that yellow is a compound colour. The other is that we generally distinguish different kinds of yellow more strictly than of other colours. "A dark yellow or orange . . . suggests its colour so little as to be called by a new name (brown), while a dark blue is blue still;" upon which I must observe that we thus distinguish degrees of impurity rather than degrees of darkness, and that an impure yellow is called brown when it is dark, and drab when it is light.

Both things, however, are explained if it is true that *natural yellows differ less from the nearest colours of the spectrum than other natural colours do.* For, in the first place, the consequence will be that there will be many yellows in nature which we could not compound by our ordinary reds and greens, and we therefore find it difficult to imagine it could be compounded by any red and green. Secondly, there will be a greater relative range, so to speak, of yellowness, which we shall naturally subdivide according to degrees of purity and brightness. It may be added that, so far as brightness is concerned, the greater maximum brightness of yellow would act in the way last described.

But is it true that our yellows differ less from the nearest colours of the spectrum than our other colours do? I certainly think this is the result of the experiments, but I will only show that it is the case with the pigments employed by Mr. Strutt. He says, indeed, that "the most saturated yellow can be compounded of red and green." So it may in the spectrum (Maxwell, *Phil. Trans.*, 1860, p. 57—84); but Mr. Strutt's yellow cannot be compounded of Mr. Strutt's red and green. On the contrary, we see from his last "calculated" equation but one, that his yellow had to be diluted with nearly two-thirds as much of his white (the brighter of the two, I presume) before it could be matched by his red and green.

We can test the matter more closely. Denoting Mr. Strutt's red, green, and blue by r, g, b, and the "primary" red, green, and blue of the spectrum by R, G, B (Maxwell, *ubi supra*, p. 74), we may thus express the former in terms of the latter:—

$$\left.\begin{aligned} r &= LR + mG + n'B \\ g &= lR + MG + nB \\ b &= lR + m'G + NB \end{aligned}\right\} (1);$$

where we know thus much about L, m, &c.; first that they are all positive, or else extremely small; secondly that, among them, the large letters must denote comparatively large quantities, and the small letters small quantities. Now, by the second "calculated" equation of the second batch, we find that Mr. Strutt's yellow is

$$\frac{1}{57}(128{\cdot}4\,r + 63{\cdot}5\,g - 49\,b);$$

and, if we substitute in this expression the expressions given above (1) for r, g, b, we shall have, for the coefficient of B,

$$\frac{1}{57}(128{\cdot}4\,n' + 63{\cdot}5\,n - 49\,N)$$

Now this must not be negative, or else must be very small in comparison with the coefficients of R and G (Maxwell, *ubi supra*, Tables VI. and IX.). Therefore N cannot be greater than $2{\cdot}6\,n' + 1{\cdot}3\,n$; that is to say, there is no more "primary" blue in Mr. Strutt's blue than about $2\frac{1}{2}$ as much as in his red, *plus* $1\frac{1}{3}$ as much as in his green. It is true that blue is rather a dark colour in pigments; but so it is in the spectrum; and N measures, not a quantity of colour simply, but its ratio to the "primary" blue of the spectrum. Either the yellow was very pure, or the red and green very impure; and, if Mr. Strutt provided himself with good representatives of natural colours, this proves my point. C. J. Monro

Jan. 20

The Primary Colours

I have been greatly interested in reading Mr. Strutt's curious experiments on colour in the last number of Nature. I am glad to see that he is able to assume as proved the theory that green and not yellow is the middle primary. The true position of green is well illustrated in Mr. W. Benson's "Principles of the Science of Colour," both by argument and by diagrams. There is, however, one piece of evidence which seems to me conclusive as against yellow, but which I have not seen noticed.

When a solid body is gradually heated to incandescence, the light given out is first *red*, then *orange*, afterwards *yellow*, and finally *white*. If yellow were a primary, it would be impossible for it to appear in this series, which is formed upon the basis of the first primary, red, by successive additions of more and more rapid vibrations. Every colour in the series except the first must be a compound. If the heat is not sufficient to generate the most rapid vibrations which the eye can appreciate, white light is not given off at all, the series terminates with the yellow. The light of a glowing coal, without flame, in an ordinary fire, rarely passes beyond the yellow stage, and such light yields to the prism abundance of red and green rays, but scarcely a trace of blue or violet.

But, if red is the first primary, and green the second, which is the third? Shall blue still sit upon the throne on which Newton placed him, when his brother yellow is deposed? I think his position has become extremely precarious, and that he would be wise to abdicate with dignity before he is ignominiously turned out as a usurper.

If the kingdom of light is really divided into three principalities, is not violet the rightful heir to the third throne? Violet is said to be a mixture of blue and red. But how should red make its appearance at the wrong end of the spectrum? If it has no definite limit, but gradually thins out from its own place to the other extremity of the spectrum, then the whole of the other colours must be more or less affected by it, and red must be the only true primary among them. If it is said that the red in violet is clearly recognised by the eye, I think it may be answered that this is only because we have been taught to think of it as a compound, and that we might just as truly say that we can see yellow in green or orange in red.

Leicester, Jan. 21 Fredk. T. Mott

Utilisation of Sewage

While heartily thanking your reviewer for the very valuable suggestions which he has given me with regard to the second edition of my "Digest of Facts relating to the Treatment and Utilisation of Sewage," I wish to point out a slight oversight which he has made.

He says, "Mr. Menzies' name, however, has somehow or other slipped out of his pages (159, 169) where he treats of this improvement on the older plans for sewage."

The fact is that page 145 has somehow or other escaped the reviewer's critical eye. On that page the following sentence occurs:—"Some of these towns, then, it will be seen, are provided with sewers much upon the plan which Mr. Menzies has the credit of having first brought prominently forward; that is to say, with impervious pipes for the sewage properly so called, and brick drains for the surface and storm water, the former being laid deeply and the latter being superficial."

I should be very sorry to have it thought that I had forgotten "to emphasise the name of the Windsor Sanitarian."

W. H. Corfield

Ocean Currents

The differences of barometric pressure to which Mr. Keith Johnston refers (Nature, Jan. 19, p. 227) have a well-ascertained geographical existence, but his suggestion that they may originate or direct the Ocean Currents is clearly inadmissible. The high pressure over a large patch of the North Atlantic to the south or south-west of the Azores—and similarly in each of the other oceanic basins—is there permanently; and whatever disturbance might be produced by it was produced once for all when the high pressure was first formed. It would then displace a certain quantity of the water over which it rested, would thrust it out, and keep that particular part of the ocean at a slightly lower level than that over which the pressure of the air was not so great. But having done this, the adjacent bodies of water would be in hydrostatic equilibrium, and the high pressure could not continue to thrust water out towards the place of low pressure. My meaning may be at once illustrated by putting one end of an open glass tube into a basin of water, and partially exhausting the air inside it. The adjacent surface is thus exposed to a higher pressure than the surface inside the tube, and a certain portion of the water is immediately thrust from the place of greater to the place of less pressure; the column of water inside the tube is raised until the weight of the excess balances the difference of pressures. At that height it remains, and no further movement takes place, so long as the relative pressures remain the same. A fluctuation of the pressures will give rise to alternate ingoing or outgoing currents, but a continuous stream in one direction can only be produced by a continuous increase or decrease of one or the other pressure.

But independently of the equilibrium, which must, so far as the pressure is concerned, be established, the difference of level caused by these differences of pressure is extremely trifling. The barometric difference between the patch of high pressure in latitude 30° and the equator is about $\frac{3}{10}$ths of an inch, or equivalent to a column of water 4 inches in length. A difference in level of 4 inches in 1,800 miles can scarcely under any circumstances give rise to a current of twenty miles an hour.

J. K. LAUGHTON

Royal Naval College, Portsmouth, Jan. 23

IT is singular that diversity of opinion should still exist as to whether ocean currents are due to the impulse of the winds, or to difference of specific gravity. That ocean currents are not caused by difference of specific gravity between the waters of equatorial and polar regions can be proved, as the amount of force from this cause acting on the ocean to produce a current, can be readily calculated.

Assuming, which is not the case, that difference in saltness between the water of equatorial and polar regions does not in any wad tend to neutralise the effect resulting from difference of temperature, in other words, that the sea in polar regions is as salt as the sea in equatorial regions, it can be shown that the force resulting from the difference of temperature, tending to produce a current towards the poles, amounts to only $\frac{1}{1820000}$ of that of gravity. For example, the force impelling a cubic foot (64lb.) of sea water at the surface of the ocean towards the poles is scarcely equal to the weight of one-fourth of a grain.* A force so infinitesimal, acting on a fluid even so perfect as water, can produce absolutely no motion. M. Dubuat found by direct experiment that it requires a force four times greater than the above to produce even sensible motion.

Ocean currents are due alone to the impulse of the wind. In the latter half of my paper on the Cause of Ocean Currents, which will shortly appear in the *Philosophical Magazine*, I hope to be able to show that the objections to this theory are founded upon misconceptions regarding the way in which winds produce the great system of oceanic circulation.

JAMES CROLL

* *Philosophical Magazine* for October 1870, p. 249.

Dr. Frankland's Experiments

IN last week's NATURE Dr. Frankland describes some experiments, apparently under the impression that they were similar to one (No. 20) published by me in NATURE, No. 36, p. 200. The results which he obtained were in reality totally different from those which I obtained, although those who read Dr. Frankland's communication are lead to believe that the results were almost wholly similar. The inference to be drawn from what he has written is that we differ merely as regards the interpretation of the nature of what was seen.

Dr. Frankland says he made use of tubes of "hard Bohemian glass," and that, on examining them "when they came out of the digester, it was evident that the *interior walls of the glass tubes had been corroded* by the enclosed fluid." After a time the "liquid in all the tubes became more or less turbid, and, in some cases, a small quantity of a light flocculent precipitate subsided to the bottom." After five months two of the tubes, which exhibited "the greatest turbidity," were selected for examination, and the "flocculent sediment" in the tubes was more especially subjected to a careful microscopical examination. This scrutiny was conducted by Professors Frankland and Huxley and Mr. Busk. Dr. Frankland then says: "So far as the optical appearances presented by the sediment go, they may be appropriately described in the terms which Dr. Bastian applied to the matter found by him in a solution of like composition, and similarly treated."

Now, that any real similarity did exist, I feel most strongly inclined to doubt, because the solution examined was not similar in constitution to my own, and because no such "flocculent sediment," as that to which Dr. Frankland alludes, ever existed in my flask.

In the experiment of mine to which reference is made, the precise quantities of carbonate of ammonia and phosphate of soda employed are not known. In this first experiment the ingredients were not weighed, although, subsequently, solutions have been prepared for me of the strength which Dr. Frankland names.

Then, although my tube with its contained solution was exposed to the same temperature as that employed by Dr. Frankland, its internal walls were not in the least corroded, and no "flocculent sediment" appeared in the solution. And, in addition, two other tubes which were prepared for me by Dr. Frankland (which did contain solutions of the same strength as those which he employed) have not had their transparency in the least impaired, although they were submitted to precisely the same temperature; neither have they shown a trace of the "flocculent sediment" previously mentioned. Seeing, however, that in one experiment (May 11th), with a solution of the same strength, a tube of English glass was employed by Dr. Frankland's assistant, and that the internal walls of this tube were corroded; and seeing, moreover, that a "flocculent sediment" did form also in this particular tube of mine, I cannot help fancying that Dr. Frankland may be mistaken as to the nature of the glass employed in his experiments. If, as in this experiment of mine, it was really English glass instead of hard Bohemian, almost the whole of the small quantity of phosphoric acid originally in the solution would probably have been deposited in the form of an insoluble phosphate of lead, and thus the character of the solution would have been entirely changed.

In my previously published experiment the fluid was examined at the end of thirty days. "When this flask was received from Dr. Frankland, the fluid was somewhat whitish and clouded. During the last ten days a thin pellicle had been seen gradually accumulating on its surface, and in the latter four or five days this increased much in thickness, and gradually assumed a distinct mucoid appearance. The fluid itself was tolerably clear, though an apparent turbidity was given by the presence of a fine whitish deposit on the sides of the glass. When the flask was opened the reaction of the fluid was found to be *neutral.* Portions of the *pellicle* were at once transferred to a glass microscope slip," &c. (NATURE, No. 36, p. 200.) In portions of this pellicle were found the "*five spherical or ovoid spores*," upon the finding of which alone I laid any stress as indicative of the presence of living things. The presence of mere particles having a movement indistinguishable from Brownian movements, has never been adduced by me as evidence that living things had been evolved in a solution, although the representations of others would lead the public to believe that I have done so.

In the face of these differences, therefore, I was somewhat surprised at the intimations contained in Dr. Frankland's letter. He believes, and would lead your readers to believe also, that the microscopical appearances presented by the "flocculent sediment" and *débris* of corroded glass obtained from his tubes were similar to the microscopical appearances of a *pellicle* obtained by me from a tube in which there had been no corrosion. This, however, I am the less inclined to believe, because I also have had the opportunity of examining a flocculent sediment and *débris* of corroded glass from a tube previously referred to, which was opened on October 21, and in which also no living things were found. Microscopical specimens of the "pellicle" and of the "sediment" are now in my possession.

Perhaps I may venture to recommend Dr. Frankland to destroy the other two tubes which are corroded, as being worthless, and to hope that, in any future experiments, he will subsequently expose his fluids to a somewhat higher temperature, and also, before immersing his experimental tubes in any fluids, that he will thoroughly satisfy himself as to the transparency of such fluids to the actinic or chemical rays of light. We are informed that his tubes were "exposed to bright diffused daylight, and sometimes to sunlight," but any amount of exposure to light would be more or less useless if strong sulphuric acid and strong carbolic acid are as black to the chemical rays of light as nitrite of amyl and other fluids have been shown to be. Dr. Frankland makes no statement concerning this very important point.

The Tails of Comets, the Solar Corona, and the Aurora, considered as Electric Phenomena

MY attention has been called to a rudely worded attack by a certain Mr. Bedford, Phil.D., on Professor Reynolds, of Owens College. This is not the first time Mr. Bedford has offended in this way. Prof. Reynolds has not seen Mr. Bedford's pamphlet.

I have. A copy was sent to Messrs. Groombridge in support of certain claims on my views about the stars. Let me hasten to assure Prof. Reynolds that, as he surmises, the views expressed in this very scarce treatise bear not the remotest resemblance to his.

I read several weeks ago Prof. Reynolds' interesting paper, the views expressed in which are, in a general way, similar to those I advocated in a paper entitled "Strange Discoveries respecting the Aurora" in *Frazer's Magazine* for February 1870. As it was quite clear to me, however, that Prof. Reynolds' views had been formed quite independently, it seemed wholly unnecessary to comment on that resemblance. I could only rejoice that so competent an authority should have been led to conclusions agreeing in general so satisfactorily with those I had deduced; and also, be it noted, with the results of the observations made on the recent eclipse. RICHARD A. PROCTOR

Browning's Spectroscope

A LETTER from Mr. Browning, in the number of NATURE for December 15th, has just come to my notice, and seems to require a word from me. I regret exceedingly that he should have supposed that I intended to imply that he had committed any impropriety in employing in his own automatic combination an arrangement of Mr. Rutherfurd's from a spectroscope which was not automatic. I did not "go out of my way" in making the allusion, but only stated what I supposed to be a fact, in order to show that the proposed arrangement of radial bars was good and practicable, having already been endorsed by most eminent authority.

At the time when the article was written, Mr. Browning had but recently published the account of his instrument, and, of course, I knew nothing about its earlier history.

On the other hand, a full description of Mr. Rutherfurd's arrangements with an illustrative figure had appeared in *Silliman's Journal* in March 1865, more than four years earlier. This article is dated December 10, 1864, and will be found in the Journal referred to: vol. xxxix., p. 129.

Possibly the tone of my allusion may have been unintentionally affected by the fact that I supposed that Mr. Browning had seen this article. In common with many other Americans, who have spoken to me about it, I thought it singular that, in describing his own instrument, he made no reference to Mr. Rutherfurd, and am very happy to find him blameless in the matter. At the same time, I think he has no ground of complaint against me for referring to the arrangement as "first devised by Mr. Rutherfurd, and since adopted by Mr. Browning;" although, if I were to write the sentence again with my present knowledge of the facts, I should put it quite differently.

Let me add also that, having seen the instrument to which Mr. Lockyer refers in his note, I cheerfully concede to him the priority in respect to the use of an elastic spring, and the half prism at the beginning of the train, as well as the idea of sending the light twice through the train by a right-angled prism at its extremity. As he has never published an account of his instrument, however, I suppose I can hardly be held blameworthy for re-inventing it, and publishing it myself. Without one unkindly feeling the words of the old poet still sometimes come to mind, "*Fereant qui ante nos nostra dixerint.*"

The magnetic record at Greenwich shows a well-marked disturbance of all the elements precisely simultaneous with the eruption observed on the sun's disc September 28th. The declination was affected to the extent of five minutes of arc, and the disturbance was compounded of two waves, following each other, and partly superposed, probably corresponding to the ejection of the two masses of protuberance-matter which are shown in the figures. C. A. YOUNG

London, Jan. 21, 1871

St. Mary's Hospital

I SEE in this week's NATURE the announcement that Dr. Wood has been appointed Lecturer on Chemistry at St. Mary's Hospital Medical School. This is an entire mistake; no appointment has yet been made, since Dr. Russell will continue to hold the post until the end of the Winter Session. The vacancy has not therefore actually occurred yet, although it will be declared shortly, and a fresh appointment made in due course.

W. B. CHEADLE,
Dean of St. Mary's Hospital Medical School

Jan. 20

[We were misled in making the announcement referred to above by our contemporary the *British Medical Journal.*—ED.]

IMPROVEMENT OF GEOMETRICAL TEACHING

A CONFERENCE was held at University College, London, on Tuesday, the 17th inst., to take this subject into consideration, and to form an Association for the improvement of geometrical teaching throughout the United Kingdom.

Previous to the meeting a large number of head and mathematical masters and others interested in the subject had given in their adhesion to the principles upon which it was proposed to form the Association. These included representatives of the following important schools:—Winchester, Eton, Harrow, Rugby, Charterhouse, Christ's Hospital, Marlborough, Wellington, Clifton, Uppingham, Sherborne, Birmingham, Dulwich, University College School, London, Repton, Durham, Manchester, King William's College, Isle of Man; Tiverton, Taunton, Leeds, Huddersfield, Nottingham, Yarmouth, Windermere, Mill-hill School, Middlesex, Middle Class School, Cowper Street, Middle Class School, Bedford, the majority of whom were present at the Conference. The movement was further supported by Dr. Hirst, F.R.S., of London University, Mr. W. Spottiswoode, F.R.S., president of the London Mathematical Society, Mr. C. W. Merrifield, F.R.S., Principal of the Royal School of Naval Architecture, South Kensington, and others.

Dr. Hirst, the president, took the chair, and resolutions were passed bearing upon the organisation and future working of the Association. It was proposed to invite the mathematicians of the country to prepare syllabuses of elementary geometry, embodying their views of the principles which should be adopted in any new text-book which is to supersede Euclid. Further particulars may be obtained by application to Mr. R. Levett, honorary secretary, King Edward's School, Birmingham.

A HINT TO ELECTRICIANS

MR. MANCE'S method for measuring the internal resistance of a single galvanic element or battery, communicated to the Royal Society at its meeting of last week, and the modifications of Wheatstone's bridge suggested by myself for finding the resistance of a galvanometer coil from the deflection of its own needle, supply desiderata in respect to easy and rapid measurement, which have been long *felt* by telegraph electricians and *needed* by other scientific investigators and by teachers of science. Year after year the latter, in their arrangement of batteries, electrodes, and galvanometers, have darkly and wastefully followed the method which from workmen we learn to call rule of thumb; while the former, with admirable scientific art, measure every element with which they are concerned, in absolute measure. How many physical professors are there in Europe or America who could tell (in millions of centimetres per second) the resistance of any one of the galvanometers, induction coils, or galvanic elements which they are daily using? How many of them, in ordering an electro-magnet, require of the maker that the specific resistance of the copper shall not exceed 16,000 (gramme centimetre-seconds)? How many times have eight Grove cells been set up to produce a degree of electro-magnetic effect which four would have given, had the professor exacted of the instrument-maker the fulfilment of a simple and inexpensive scientific condition, as submarine telegraph companies have done in their specifications of cables? If every possessor of an electro-magnet were to cut a metre off its coil, weigh the piece, measure its resistance, and send the result to NATURE, and if every maker of Ruhmkorff coils would do the like for every coil of copper wire designed for his instruments, a startling average might be shown. And what of the items? I venture to say that (provided the instruments of the great makers are not excluded) specific resistance above 30,000 would not be a singular case. I could tell something of galvanometers of 1869, comparable only to submarine cables of 1857. I refrain:—but let makers of galvanometers, Ruhmkorff coils, and electro-magnets beware; surely NATURE will find them out if they do not reform before 1872. W. THOMSON

THE GAUSSIAN CONSTANTS OF TERRESTRIAL MAGNETISM

I THINK you will be doing good service to the cause of Natural Science by giving insertion in your valuable pages to the following translation of a notice which appeared in No. 1,825 of the *Astronomische Nachrichten* (Vol. 77, p. xi.), on the subject of Prof. Petersen's re-computation of the Gaussian Constants of Terrestrial Magnetism, in aid of which the British Association at their last meeting voted a grant of money. It has been communicated to me by Prof. Erman of Berlin, who, in reference to the grant in question, writes as follows:—"This new act of British generosity would in other times have scarcely needed a special mention, being equalled by so many former ones of the same kind; but in the present moment, when the raging war makes petty jealousies spring up between our two befriended [friendly] nations, it is a most sacred duty to publish the fact of two Prussians having found in England a most generous and most wanted help for their scientific endeavours."

Mr. Petersen's calculations are progressing in a very desirable manner, and he hopes fully to bring them to their end (D.V.). J. F. W. HERSCHEL

Collingwood, Jan. 21

TRANSLATION

"We learn by a communication from Prof. Erman that M. Petersen, of Kiel, has undertaken to extend his great work on Terrestrial Magnetism, so as to afford for the whole earth, and for the epoch 1829, a *Fundamental Determination of the Potential Constants*, which, according to laws yet unknown, are subject to secular variation. From the knowledge of these fundamental values so obtained by the researches of Erman and Petersen, will then come to be securely connected, as a second step in advance, the determination of the laws of secular change. Since, however, the material obstacles to so laborious a work, with whatever personal devotion, would have proved insurmountable without public aid, it becomes our duty most gratefully to announce that such aid has been granted from the same quarter which afforded it to the earliest portion of this undertaking. The British Association for the Advancement of Science, at its last annual meeting, has appointed a committee, consisting of Sir J. Herschel and Prof. A. Erman, for the purpose of engaging M. H. T. R. Petersen to prosecute the continuation of his computations of the constants in question for 1829, so as to embrace all observations not included in the previous calculations, and to this end has placed a sum of 50*l*. at their disposal.

"In pursuance of this object Prof. Erman addresses to the readers of this notice his request for the communication of citations of, or references to, works and treatises or essays in which may be found recorded measured values for any station of the globe, of the magnetic *declination*, *inclination*, and *intensity* during any portion of the last ten years, as also any researches on the annual variations of these elements at determinate stations. Of course it is not meant to call for even an approximately complete catalogue of works of this kind, to furnish which would of itself require no small amount of labour. But many astronomers [and others] must have access to a variety of journals, accounts of travels, records of measures and observations, &c., which may not have come under the notice of Messrs. Erman and Petersen, notices of which, communicated to the Editor of the *Astronomische Nachrichten* * in the form of a letter, with a postcriptum or memorandum such as:—Magnetic Observations for 18 . . are to be found in . . . Volume . . . page . . are requested."

* Prof. Dr. C. A. F. Peters, Direktor der Sternwärte in Altona.

ACCOUNT OF THE AUGUSTA ECLIPSE EXPEDITION

IN consequence of the unfortunate wreck of the *Psyche* on a sunken rock on the coast of Sicily, about nine miles north of Catania, the arrangements of the Sicilian Expedition were considerably modified. Catania was made the headquarters of the expedition, and the garden of the Benedictine Monastery was given up by the authorities of the city to the English and American observers. It was finally arranged that Prof. Roscoe should take charge of the Etna Expedition, and I was asked by Mr. Lockyer to take charge of the Expedition to Augusta. Mr. Brett, Mr. Burton, Mr. Clifford, Mr. Ranyard, Mr. Samuelson, and myself formed the party.

It was also arranged with Mr. Ranyard at Catania, that on the morning of the 22nd, he and another of our party should drive some miles up from Augusta in the direction of the hills of Carlentini, to observe the Eclipse. At Augusta we were to live in camp, and Colonel Porter, with a body of sappers, had been landed there by the *Pysche* on her way to Naples.

Mr. Brett and Mr. Ranyard went first to Augusta to make arrangements with Colonel Porter for our encampment and observatory, and they met with every assistance from the Syndic of the City of Augusta, and were very kindly received by the Italian astronomers, among whom were Prof. Cacciatore, Prof. Donati, Father Secchi, and Father Denza, who were stationed inside the fort. Our encampment, and a wooden observatory sixty feet long, were pitched on the southern slopes of the glacis of the fort, with a full view of the sea to the east.

I cannot speak too highly of the way in which Colonel Porter exerted himself to make all arrangements satisfactory and complete, and even to introduce elements of comfort into our camp life; and the energetic way in which his men carried out his instructions is beyond all praise. Up to Monday the 19th, the terraces of the Monastery at Catania were made the general practising ground, and those who were to observe for polarisation, except Mr. Ranyard, who was at Augusta, tested and compared their instruments for rapidity of correct observation, and for delicacy.

For my own telescope I had two eye-pieces, one with plates of double-rotating quartz, and the other with a Savart polarimeter. When the polarisation was not very strong, I found the polarimeter more delicate than the biquartz for detecting the plane of polarisation, and with it I was able to measure the amount of polarisation readily. On observing the same points with Mr. Griffiths, who also used a Savart polarimeter, we found that in from ten to fifteen seconds we could determine the plane and amount of polarisation, and in some cases we found that our readings for both were absolutely identical.

At about 6.30 on Monday evening, and again soon after 7 o'clock, when Mr. Clifford and I were on the sea on our way to Augusta, we saw a brilliant display of the zodiacal light, consisting of brilliant pink streamers, stretching up perpendicularly to the horizon, the planet Jupiter being just on the most brilliant streamers. Towards the north and round the horizon there were also streamers and a faint hazy light, and the sky became covered with a pinkish mauve colour. One of these displays was also seen by the rest of our party at Augusta.

As the evening grew darker, there was strong phosphorescence on the sea. The drops scattered by the oar as it struck the water glowed with phosphorescent light, and the forms of the eddies, caused by the bending of the oar, were distinct and brilliantly illuminated.

At Augusta, through the kindness of Prof. Cacciatore and Father Denza, I was able to obtain the latitude and longitude, as well as the local times of the different phases of the Eclipse :—

Latitude of Fort Augusta	37° 14′ 0″·6	N.
Longitude ,, ,, ...	1h 0′ 52″·2	E. of Greenwich.
Local time of beginning of totality..	2h 1′ 56″·7	
,, middle ,, ...	2h 2′ 52″·1	
,, end ,, ...	2h 3′ 47″·5	
Making the duration of totality	1′ 50″·8	

The barometer fell from the morning of the 20th to the morning of the 22nd, then rose a little, and again began to fall about 12 o'clock, and was lowest about the time of totality. On the evening of the 21st the Italian astronomers reported to us the bad state of the weather throughout Italy and Sicily, the wind being westerly, and that a sirocco was expected everywhere. From about 2 o'clock in the night there was a heavy storm of wind and rain, with thunder and lightning, and our tents were in danger of being blown away. By 6 o'clock the rain had ceased, and the wind moderated, but there were still frequent flashes of lightning on the eastern horizon ; in half an hour thick clouds had again covered the sky, and we had rain. The wind again became violent, and swept away the clouds, but the weather did not look promising.

According to previous arrangement, Mr. Ranyard started in a carriage to go up to the hills, and Mr. Samuelson accompanied him, and they took two sappers with them.

When the moon had entered about one-third of her diameter Mr. Brett, with his 8·5 inch reflector, observed the corona round the limb of the sun as a hazy light most brilliant nearest the sun's limb, and the limb of the moon could be traced on this corona for about 2′ from the cusps. On these points Mr. Burton confirmed Mr. Brett's observations. Soon after a sudden chill was felt, and there was a sudden change in the light. About three minutes before totality there were brilliant and very remarkable patches of red and yellow light on the cloud to the right of and below the sun. Mr. Burton describes them as bows, apparently concentric with the sun. During the morning Mr. Burton had been able to indicate the positions of some of the most remarkable prominences, but the stormy wind prevented him from mapping them accurately. Father Secchi had also kindly sent us the positions of those which he had observed.

Just before totality, Mr. Burton saw and made a diagram of a prominence at the lower horn, and saw several lines in the spectrum of the chromosphere between D and E. Using his large telescope Mr. Brett was able to make a sketch of the corona during the totality.

On account of the cloud, Mr. Burton was able to make only one of the four observations he had hoped to make on the Corona with his five-inch equatorial and spectroscope. At the beginning of totality, placing his slit tangential and very near to the east limb, but not on a prominence, a bright line was distinctly seen in the spectrum, very near E, and a little less refrangible. The line was less defined than the hydrogen lines of the prominence. No dark lines were seen on the Corona.

At the end of totality, Mr. Burton had a momentary glimpse of the Corona, but had no time to get the telescope on it before the totality was over. With regard to the amount of light, he says that it was sufficient to see a pencil diagram at a distance of two feet from the eye. I can confirm him in the view that the darkness was not intense, and have no doubt that the diffusion of light by the cloud gave us more light than we should otherwise have had. Venus and some stars were seen.

Colonel Porter had kindly volunteered to make a sketch of the Corona, but the cloud prevented him from obtaining any satisfactory result.

I did not see the Corona at the beginning of totality with my telescope. As the band of sunlight became exceedingly thin, and at the instant of its disappearance broke up into sections, I could not decide whether the lunar mountains had pierced the rim of light, or whether the dense cloud coming over the moon had cut out certain portions of the rim before obscuring the whole.

After this, I could detect nothing of the disc of the moon for a full minute, then the cloud became thinner, and I found that by slowly moving the telescope I had kept the moon in the centre of the field. At the top and bottom, the limb was visible, but no light was seen outside it at these points. I saw light of the Corona near the point of beginning of totality covering some 20° of the limb, and also a trace of light near the point of emergence. I could not perceive any colour on these portions of the Corona, nor could I detect any difference of colour on the two plates of my bi-quartz, the line of division of which was at right angles to the sun's path, *i.e.*, inclined at 15° to the vertical. The moon was again observed, and again I detected light near the point of emergence, and placed the line of division of my bi-quartz radial to the moon, having the light in the centre of the field, but I could detect no trace of colour on the two parts of the crystal, showing that the bi-quartz was not sufficiently delicate to detect the polarisation under such unfavourable circumstances. The rim then became continuous, and the totality was over.

Mr. Clifford observed polarisation on the cloud to the right and left and over the moon, in a horizontal plane through the moon's centre, and found the plane of polarisation to be inclined at from 15° to 20° to the vertical towards the west. At his last observation, which was on the moon, when it could be seen near the end of totality, he determined the plane of polarisation to be vertical.

The comparisons made at Catania, as well as a comparison of my observations with Mr. Clifford's, seem to show that bands, rather than a difference of shades of colour, should be employed to detect delicate polarisation.

Mr. Ranyard had a very clear view at Villasmunda, although it was raining during the totality, and made *three* observations, two of which he described to me as agreeing with what should be observed in the case of radial polarisation.

Mr. Samuelson and the two sappers made independent rough drawings of what they saw, and their drawings agree well as to the Corona and the positions of the rays. Mr. Samuelson also used a Nicol's prism, with Savart's bands, to determine the polarisation on the sky at three points, and at two of these points found the plane of polarisation vertical.

I have not yet seen the details of Mr. Ranyard's or of Mr. Samuelson's reports.

Although the other successful observers of the Eclipse in Sicily were not attached to the Augusta expedition, of which Mr. Lockyer had put me in charge, I may add that at Syracuse the weather was favourable, and Mr. Griffiths was able to determine the plane and amount of polarisation at different points of the Corona ; also, that Messrs. Brothers and Fryer were able to take some good photographs of the Corona, one of which is very remarkable for its clear definition of the Corona and of the rays extending out to a distance of two diameters from the moon's limb. This photograph and a careful sketch of the Corona by Mr. Watson, one of the American observers, show a very remarkable agreement, and prove the existence of the remarkable dark cusps on the Corona.

At Augusta, two bright lines were seen in the spectrum of the Corona by Father Denza, one of the Italian astronomers, but no dark lines have been seen.

We experienced every kindness from the Italian astronomers at Augusta and from the authorities ; and, on the day after the Eclipse, we were invited by the Syndic of the City to meet the Italian Astronomers at a grand public dinner given by the City in honour of our visit.

King's College, Jan. 16 W. G. ADAMS

FLOWER'S OSTEOLOGY OF THE MAMMALIA *

PROF. FLOWER'S "Introduction to the Osteology of the Mammalia" is a thoroughly satisfactory addition to English anatomical literature. It supplies a much-felt want, and combines the rarely united qualities of completeness with brevity; and, while thoroughly scientific, is remarkable for its clearness and simplicity of expression.

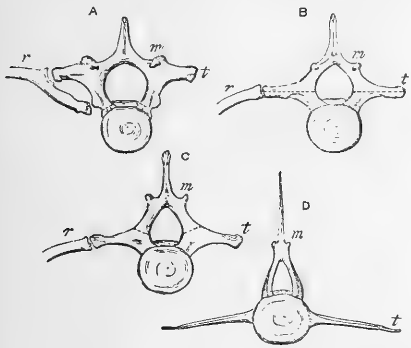

FIG. 1.—Anterior surface of vertebræ of Dolphin (*Globiocephalus melas*), ¼. A fifth thoracic; B seventh thoracic; C eighth thoracic; D first lumbar; *r* rib; *m* metapophysis; *t* transverse process. The dotted lines indicate the position of the neuro-central suture.

Of convenient size for the pocket of the student, it consists of three hundred and thirty-seven pages of excellent letter-press, and is illustrated by one hundred and twenty-six woodcuts, nearly all original. These are exceedingly well drawn, and make the book attractive in appearance (though it is to be regretted that they have somewhat suffered in the printing), while the subjects chosen have evidently been selected with great care as regards their utility in illustrating the text.

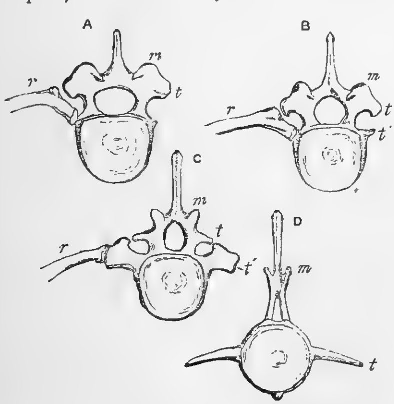

FIG. 2.—Anterior surface of vertebræ of Sperm Whale (*Physeter macrocephalus*), $\frac{1}{24}$. A eighth thoracic; B ninth thoracic; C tenth thoracic; D fifth lumbar; *r* rib; *m* metapophysis; *t* upper transverse process; *t'* lower transverse process

* "An Introduction to the Osteology of the Mammalia." By W. H. Flower, F.R.S., Hunterian Professor of Comparative Anatomy and Physiology. (London: Macmillan and Co.)

The first chapter contains a very short account of the classification of the Mammalia, accompanied by an interesting diagram "intended to exhibit the relationships which appear to exist between the different groups of the Mammalia." The small size of this diagram hardly affords space enough to express fully the degrees of affinity between the different groups. It is owing to this, perhaps, that the Carnivora are separated from the Ungulata by a less interval than that which divides them from the Insectivora, and that the Hominina are but very slightly more approximated to the Simiina than are the latter to the Lemurina, although the structural difference between the last-named groups and all the higher primates are so great that Professor Flower himself hesitates "whether they should be associated with the monkeys, or should constitute a distinct order by themselves." Nevertheless, the diagram is very instructive, and well expresses the more important relationships existing between the groups as far as their affinities have been demonstrated, or shown to be probable by the present state of zootomical science.

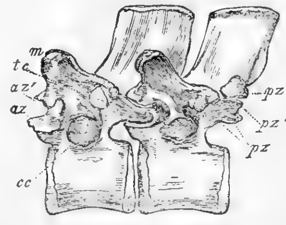

FIG. 3.—Side view of twelfth and thirteenth thoracic vertebræ of Great Anteater (*Myrmecophaga jubata*), ⅔ *m* metapophysis; *tc* facet for articulation of tubercle of rib; *cc* ditto for capitulum of rib: *az* anterior zygapophysis: *az*¹ additional anterior articular facet; *pz* posterior zygapophysis; *pz*¹ and *pz*² additional posterior articular facets.

Thus the distinctiveness, yet close affinity, between the ordinary Carnivora and the seals is made evident, as also the remoteness of the Sirenia from the Cetacea, and the approximation of the former to the Ungulata.

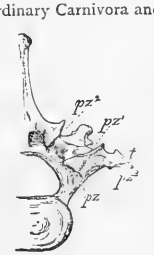

FIG. 4.—Posterior surface of second lumbar vertebra of Great Anteater, ⅔ *t* transverse process; *pz* posterior zygapophysis; *pz*¹, *pz*², and *pz*³, additional posterior articular facets.

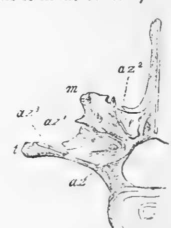

FIG. 5.—Anterior surface of third lumbar vertebra of Great Anteater. ⅔ *t* transverse process; *m* metapophysis: *az* anterior zygapophysis: *az*¹, *az*² and *az*³, additional anterior articular facets.

The complex relationships of the subordinate groups of hoofed beasts are also well exhibited, and though, perhaps, some objection might be made to the position of the anomalous little group, Hyracoidea, it would be difficult to put it in any other spot not also open to criticism.

A laudable desire not to increase too much the bulk of his volume has, doubtless, induced the author to make his chapter on Classification so very brief. It is, nevertheless, to be hoped that, in the next edition, it may be made at least as long again; as, in its present condition, the student can hardly find in it all the information necessary for the comprehension of the other parts of the work.

Thus, in describing the skull, the family names *Cebidæ* and *Hapalidæ* are used, as also *Ursidæ*, *Procyonidæ* and *Mustelidæ*, though nothing is said as to these groups either in the text of the first chapter, or in its explanatory diagram. The addition of three more pages would do away with this imperfection.

After the introductory chapter on Classification we have the skeleton as a whole, the vertebral column with its several regions, the sternum, ribs, skull, shoulder girdle, arm and hand, pelvic girdle, leg and foot, successively described in eighteen different chapters. The maximum degree of complication in the Mammalian spine (*i.e.*, in that of the great ant-eater) is for the first time clearly and accurately described.

In each case the part of the skeleton treated of is first described in its normal and typical condition, and afterwards each order of mammals is passed in review, and

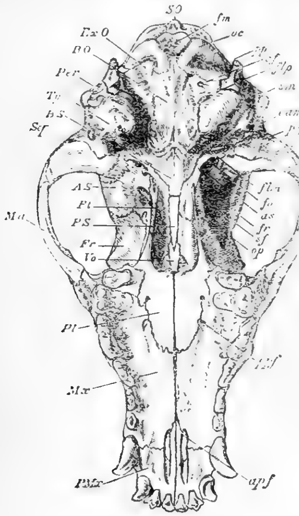

FIG. 6.—Under surface of the cranium o a Dog, ½. *SO* supraoccipital; *ExO* exoccipital; *BO* basioccipital; *Per* mastoid portion of periotic; *Ty* tympanic bulla; *BS* basisphenoid; *Sq* zygomatic process of squamosal; *Ma* malar; *AS* alisphenoid; *Pt* pterygoid; *PS* presphenoid; *Fr* frontal; *Vo* vomer; *Pl* palatine; *Mx* maxilla; *PMx* premaxilla; *fm* foramen magnum; *oc* occipital condyle: *pp* paroccipital process; *cf* condylar foramen; *flp* foramen lacerum posterius; *sm* stylo mastoid foramen; *eam* external auditory meatus; *pgf* postglenoid foramen; *gp* postglenoid process; *gf* glenoid fossa; *flm* foramen lacerum medium; *fo* foramen ovale; *as* posterior opening of alisphenoid canal; *fr* foramen rotundum and anterior opening of alisphenoid canal; *sf* sphenoidal fissure or foramen lacerum anterius; *op* optic foramen; *ppf* posterior palatine foramen; *apf* anterior palatine foramen.

the leading modifications which such part presents in each ordinal group are stated.

Thus, with regard to the skull, we have first a chapter on the skull of the dog as a type—an admirable description, and a model for writers on kindred subjects from its completeness, its clearness, its thoroughness, and its simplicity. Next, we have a chapter on the skull as it exists in the orders Primates, Carnivora, Insectivora, Chiroptera, and Rodentia. After this follows a chapter on the skull in the Ungulata, Hyracoidea, and Proboscidia; then one on the same part in the Cetacea and Sirenia, and finally one on the skull in the Edentata, Marsupialia and Monotremata. This last chapter may hereafter be judiciously expanded. The skulls of the Echidna and Ornithorhynchus alone might well take up half the space which is here allotted to these three orders.

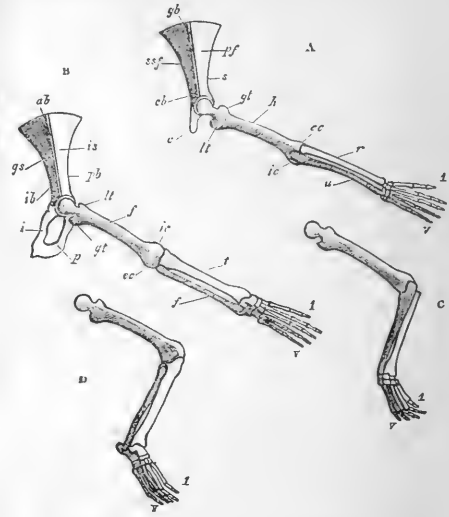

FIG. 7.—Diagrammatic representation of the positions of the limbs of Mammalia. The preaxial border is left light, the postaxial border shaded. in all the figures. Limbs of the right side are represented in all cases. A dorsal aspect of the anterior extremity in its primitive unmodified position; *gb* glenoid border of the scapula: *s* spine; *cb* coracoid border; *ssf* subscapular fossa; *pf* postscapular (infraspinal) fossa; *c* coracoid; *h* humerus; *gt* greater, radial, or preaxial tuberosity; *lt* lesser, ulnar, or postaxial tuberosity; *ec* external (in the modified position), radial, or preaxial condyle; *ic* internal, ulnar, or postaxial condyle; *r* radius; *u* ulna; I pollex; V fifth digit. B dorsal aspect of the posterior extremity in the same position; *ab* acetabular border of the ilium; *pb* pubic border; *ib* ischial border; *gs* gluteal surface; *is* iliac surface; *i* ischium; *p* pubis; *f* femur; *lt* lesser, tibial, or preaxial trochanter; *gt* greater, fibular, or postaxial trochanter; *ic* internal (in the modified position), tibial, or preaxial condyle; *ec* external fibular, or postaxial condyle; *t* tibia; *f* fibula; I hallux; V fifth digit; C the anterior extremity, with the humerus in the same position, but the elbow and wrist joints bent; D the posterior extremity in the same position.

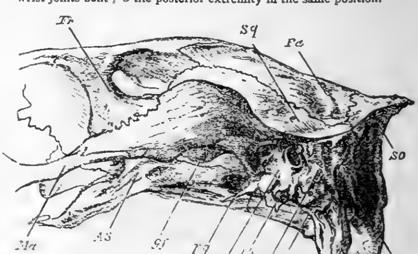

FIG. 8.—Side view of the posterior part of the skull of a Horse, ½. *Fr* frontal (the line points to the postorbital process); *Sq* squamosal; *Pa* parietal; *SO* supraoccipital; *ExO* exoccipital; *oc* occipital condyle; *pp* paroccipital process; *Per* mastoid portion of periotic; *pt* post-tympanic process of squamosal; *th* tympanohyal; *Ty* tympanic; *pg* postglenoid process of squamosal; *As* alisphenoid (the line points to the plate of the bone which bridges over the alisphenoid canal); *Ma* malar.

The chapters on the hand and foot (Manus and Pes) are excessively instructive and interesting; the better to understand the conditions presented, the author steps beyond the limits of the class Mammalia and exhibits the condition of the manus in a water tortoise (*Chelydra serpentina*). At the end of the work is a chapter on "The Correspondence between the Bones of the Anterior and Posterior Extremity and the Modifications of the Positions of the Limbs," and this is the only speculative and theoretical portion of the book. All the rest is a plain and clear statement of observed facts.

Some may be disposed to regret that there is not more "theory" in the work, but the reviewer believes that, considering the scope and object of the treatise, the introduction of theoretical views would be a blemish rather than a gain.

The work is addressed to students who are in earnest and really want to learn "Comparative Anatomy." Do such need to be attracted or encouraged by brilliant or startling theories, or will, on the other hand, they follow teaching which is simply the clear expression of actual facts? To this question it may be replied *solvitur ambulando.* Last year Professor Flower delivered in the theatre of the Royal College of Surgeons the very lectures which are now being reviewed, and the attendance of students was most remarkable, not only as to numbers who came but also as to their perseverance and constancy in attending.

The book is eminently a student's book. Obscurities of expression and unnecessary technicalities are carefully avoided; and any youth who provides himself with the bones of a dog, and reads it patiently, referring with care to his dog-bones all the while, may become a respectable osteologist. While if such a youth has access to a museum like that of the College of Surgeons, he may, with this work in his hand, lay the foundation of a really good knowledge of comparative anatomy; for every anthropotomist and teacher of human anatomy will admit how readily a knowledge of "soft parts" is acquired by one who thoroughly "knows his bones."

An excellent exercise for a student would be to take the skull of a rabbit and a pig, and write out a detailed description of each, modelled on the author's description of that of the dog.

Although the work is of such moderate bulk, yet owing to its convenient arrangement, and the thorough knowledge of his subject which the author professes, it is possible, by referring to it, to get an answer to almost any ordinary question respecting the bony structure of any mammal.

Professor Flower's new human bone, the *tympano-hyal* (first described by him at the Liverpool meeting of the British Association), is shown to exist in other mammals, being very large, *e.g.* in the horse and the sheep.

Amongst so great a mass of facts, it is impossible but that there should not be some inaccuracies, without the slightest discredit thereby accruing to the author; for the laws of animal structure being but empirical, a "black swan" is at any moment liable to turn up and falsify the simplest and most useful generalisation. Thus it may turn out that the generalisation, "the *Simiina* are remarkable in never having an ossified stylohyal," is not strictly accurate, but the author having examined hundreds of skulls and never having found one so furnished, was amply justified in making the assertion. Any attempt to depreciate a work by carping criticism upon details of that kind can result only in discredit to the critic himself.

In conclusion, the reviewer is of opinion that Prof. Flower's "Osteology" should be warmly recommended to all students of comparative anatomy; while even to many advanced zoologists it will prove a work not only of much interest, but one conveying substantial, important, and trustworthy information.

F. R. S.

NOTES

So far as the delegates are concerned, the amalgamation of the Ethnological and Anthropological Societies is complete, under the name of the Anthropological Institute of Great Britain and Ireland, and the separate societies have ceased to exist. All property, effects, debts, and liabilities are to be taken over by the new society. The new officials taken from the two societies are: President, Sir John Lubbock (E.), Vice-Presidents, Prof. Huxley (E.), Tylor (E.), Prof. Busk (E.), Dr. Charnock (A.), Dr. Beddoe (A.), G. Harris (A.). Treasurer, Flower (E.). Council.—Blackmore (E), Bohn (E.), Archibald Campbell (E.), Hyde Clarke (E., A.), Boyd Dawkins (E.), Dunn (E.), David Forbes (E.), Col. Lane Fox (E., A.), T. M'K. Hughes (E.), M'Lennan (E.), Pusey (E., A.), Braybrooke (A.), W. C. Dendy (A.), Dr. King (A.), F. G. H. Price (A.), Dr. Harcourt (A.), Des Ruffieres (A.). Director, C. Staniland Wake (A.); Assistant-editor of the Journal, F. W. Rudler (E.). The last meeting of the Ethnological was held on Tuesday, and the last meeting of the Anthropological will be held on Tuesday next, when the old arrangement will cease, and other meetings will be fixed by the new council.

A DETERMINATION to take advantage of any opportunity for making scientific inquiries, is the principal feature of the present crisis among French scientific men. It is carried so far that the French Institute has appointed a committee to inquire into the effects of the shelling as well on the buildings as on the inhabitants. The specialities presented by the wounds have been reviewed in a very able essay, written by Baron Larey, in the *Revue des Cours publiques*, published by Baillière, but which has not appeared regularly. Some other essays on the same subject have been written by different medical men in the same periodical, and in some political papers.

THE increase of the mortality is a feature of the present crisis in Paris. The winter number of deaths is generally 1,000 or 1,200 a week; but in the last few weeks it has amounted to 3,000. This is not owing to any particular epidemic, although the small-pox has destroyed many victims. The larger amount of fatal cases is owing to the exposure, the want of proper food suited for infants and invalids, and the scarcity of fuel. Moral causes have also seriously affected invalids and old persons to a very large extent. Affections of the lungs are prevalent in that portion of the population.

THE large conservatory for *Orchidaceæ* in the *Jardin des Plantes* at Paris has been destroyed by a Prussian shell. The glass-work was broken, and the plants, which are so delicate, were lost without any hope of recovery. The losses are very serious, as the collection had many valuable specimens obtained from the occupation of Mexico, and from the exertions of the French Scientific Commission, which had been sent to America to explore the Empire of the unfortunate Maximilian. M. Chevreuil, the Director of the Museum, has addressed to the Academy of Sciences the following protest:—"The garden of medicinal plants, founded in Paris by an edict of King Louis XIII., dated January 3, 1626, became a Museum of Natural History on the 23rd May, 1794. It was bombarded in the reign of William I., King of Prussia, Count Bismarck being Chancellor, by the Prussian army, on the night of the 8th-9th January, 1871. Until then it had been respected by all parties, and by all national and foreign authorities. Paris, January 9, 1871." The Academy has determined that the protest of M. Chevreuil shall be printed at the head of its reports, and the Committee of Professors of the Museum have decided that a marble monument, with an inscription of the protest, shall be placed in one of the galleries of the building, surrounded with projectiles thrown from the enemy's batteries.

THE Polytechnic School has been opened at Bordeaux. M. Gambetta delivered an inaugural address. The director is M. Serrey, Member of the French Academy; but the larger number of the professors are now besieged in Paris, serving in the ranks of the National Guard. They mostly belong to the artillery. Among them are M. Janin, Professor of Physics; M. Laussedat, Professor of Topography; M. Moutard, Professor of Mathematics; M. Manheim, Professor of Descriptive Geometry.

ARRANGEMENTS for instruction in Practical Chemistry have now been completed at the London Institution, Finsbury Circus, by the opening of the Chemical Laboratory, under the direction of Dr. Henry E. Armstrong, for the reception of students requiring instruction in Analytical Chemistry and the methods of Original Investigation. The evening class for Elementary Chemical Analysis will commence work on Feb. 13, and will meet three times a week, on Monday, Wednesday, and Friday, from 6 to 8 P.M. from February to May. All students must be nominated by a proprietor, and the sons of proprietors have an advantage in the fees charged.

THE Young Men's Christian Association of New York announces a course of popular scientific lectures by Dr. Doremus, on the "Triumphs of Modern Science." "The subject is an interesting one, but we regret," says the *New York Technologist*, "to see that the Association has placed the price of tickets at $1\frac{1}{2}$ dols. per lecture, or 5 dols. for the course of four. At this rate, many young men who would otherwise attend and be interested, will prefer to pay a less amount and visit Booth's, or even the opera-house of Jim Fisk, jun. We presume that the managers will claim that the enormous expenses incurred for chemical and physical illustrations render this high price necessary. This may be true in their case, but it is a pity that they and their lecturer should forget that neither Science itself nor its popularisation depends upon magnificent spectacular effects. It this were the case, then Tweed, Sweeny, and Hall, with their free entertainments given every 4th of July at the expense of the city, can beat any scientific lecturer in the country, and even Fisk, with the gorgeous scenery of his Twelve Temptations, will prove more attractive than Huxley or Tyndall. A good experiment, so extensive as to be visible in all parts of the audience hall, and so pertinent that it gives a perfect illustration of the point under discussion, is a thing that we admire above all things. But the burning of a pound of potassium, merely for the sake of making a blaze and a smoke; the burning of diamonds, which, when performed on the lecture table of a popular audience hall, proves nothing, and is the sheerest mountebankery; the dragging in of an aquarium, merely for the sake of advertising the maker's name; and in short, everything that does not aid the hearer in obtaining clear ideas in regard to the matter in hand, ought to be rigorously excluded. The simplest experiment, performed with the cheapest apparatus, becomes beautiful and interesting beyond any display of fireworks, when it clearly illustrates some great physical truth, while the most gorgeous display will, of itself alone, fail to excite that intellectual interest that is so far superior to mere physical emotion. In the name of Science, therefore, and of that intellectual progress, of which our Young Men's Christian Association should be the promoters and advocates, we protest against a system which degrades the scientific lecture to a level with the performances of Houdin or Signor Blitz." Sensible language this, and deserving of note in this country as well as America.

WE learn from the *American Technologist* that the scientific lectures delivered and to be delivered this session before the American Institute are as follows:—Tuesday evening, December 20, 1870, The Struggles of Science, by George B. Loring, M.D., of Salem, Mass.; Tuesday evening, December 27, 1870, How we stand and walk, by Prof. Burt G. Wilder, of Cornell University, Ithaca, N.Y.; Friday evening, January 6, 1871, The Triumphs of Modern Surgery, by Prof. F. H. Hamilton, of Bellevue Hospital Medical College, New York; Friday evening, January 20, 1871, On Water, by Prof. C. F. Chandler, of Columbia College, New York; Friday evening, January 27, 1871, On Tides and Tidal Currents, and their effects upon Harbours, by J. E. Hilgard, of the U.S. Coast Survey, Washington, D.C.; Friday, February 3, 1871, On Light, by Henry Morton, President of Stevens Institute, Hoboken, N.J. These lectures are free to members of the Institute and their families, and are an evidence of the earnest work which this association is accomplishing in the way of the diffusion of knowledge.

THE centenary anniversary of the birthday of Humboldt was celebrated in Boston by the raising of a subscription to the amount of 7,040 dollars, which has been placed in the hands of the trustees of the Museum of Comparative Zoology as a Humboldt Scholarship for the benefit of young and needy persons engaged in study at the Museum, and the officers of the Museum have formally accepted the trust.
